(Received 10 June 2015; published 14 September 2015)

The dynamics of precessing binary black holes (BBHs) in the post-Newtonian regime has a strong timescale hierarchy: the orbital timescale is very short compared to the spin-precession timescale which, in turn, is much shorter than the radiation-reaction timescale on which the orbit is shrinking due to gravitational-wave emission. We exploit this timescale hierarchy to develop a multiscale analysis of BBH dynamics elaborating on the analysis of Kesden *et al.* [Phys. Rev. Lett. 114, 081103 (2015)]. We solve the spin-precession equations analytically on the precession time and then implement a quasiadiabatic approach to evolve these solutions on the longer radiation-reaction time. This procedure leads to an innovative “precession-averaged” post-Newtonian approach to studying precessing BBHs. We use our new solutions to classify BBH spin precession into three distinct morphologies, then investigate phase transitions between these morphologies as BBHs inspiral. These precession-averaged post-Newtonian inspirals can be efficiently calculated from arbitrarily large separations, thus making progress towards bridging the gap between astrophysics and numerical relativity.

I. INTRODUCTION

Observations suggest that astrophysical black holes are generally spinning [1–3] and can form binary systems [4]. Spinning binary black holes (BBHs) are a promising source of gravitational waves (GWs) [5–7] for current and future detectors [8–15]. BBH dynamics is remarkably complex and interesting, especially when both BBHs are spinning. BBH systems have three angular momenta, the two spins and the orbital angular momentum, all coupled to each other. Spin-orbit and spin-spin couplings cause these angular momenta to precess, changing their orientation in space on the precession timescale [16,17]. On the longer radiation-reaction timescale, GWs take energy and momentum out of the system, thus shrinking the orbit [18,19]. These emitted GWs encode all the richness of the precessional dynamics but are also more challenging to detect and characterize than GWs emitted by nonprecessing systems [20–27].

Expanding on the analysis in our previous paper [28], we introduce a multi-timescale analysis of the dynamics of

spinning, precessing BBHs. Multi-timescale analyses are commonly used in binary dynamics. For example, in eccentric binaries the orbital period, periastron precession, and radiation-reaction timescales usually differ by orders of magnitude; the dynamics of these systems can be studied using techniques that explicitly exploit this timescale hierarchy, such as osculating orbital elements [29] or the variation of constants [30]. Exploiting timescale hierarchies leads to deeper understanding of the dynamics because different physical processes are decoupled and individually analyzed.

Precessing BBHs evolve on three distinct timescales:

- (1) BBHs orbit each other (changing the binary separation \mathbf{r}) on the orbital time $t_{\text{orb}} \sim r^{3/2}/(GM)^{1/2}$;
- (2) the spins and the orbital angular momentum change direction on the precession time $t_{\text{pre}} \sim c^2 r^{5/2}/(GM)^{3/2}$;
- (3) the magnitudes of the orbital energy and angular momentum decrease on the radiation-reaction time $t_{\text{RR}} \sim c^5 r^4/(GM)^3$.

Here $r = |\mathbf{r}|$ is the magnitude of the binary separation, M is the total mass of the binary, and prefactors of order unity have been omitted. In the post-Newtonian (PN) regime, $r \gg GM/c^2$ and these timescales are widely separated:

$$t_{\text{orb}} \ll t_{\text{pre}} \ll t_{\text{RR}}. \quad (1)$$

*d.gerosa@damtp.cam.ac.uk†kesden@utdallas.edu‡u.sperhake@damtp.cam.ac.uk§eberti@olemiss.edu||rossma@rit.edu

BBHs complete many orbits before their angular momenta appreciably precess, and the angular momenta complete many precession cycles before the separation decreases significantly.

The first inequality ($t_{\text{orb}} \ll t_{\text{pre}}$) has been widely exploited to understand spin dynamics and approximate the GW signal. This approximation forms the foundation of the orbit-averaged spin-precession equations for adiabatic quasicircular orbits examined extensively in the pioneering study of Apostolatos *et al.* [16] and later extended by Arun *et al.* [31,32]. Using these equations, several authors have systematically explored the physics of spin precession and their implications for GW detection [33,34] and astrophysics [35,36]. Following the early work by Schnittman on spin-orbit resonances [37], PN spin dynamics has been used to predict the final spins [36] and recoils [35,38] following BBH mergers, select initial conditions for numerical-relativity simulations [39], characterize formation scenarios for stellar-mass BH binaries [40], and address the distinguishability of these scenarios by future GW observations [41–43].

The second inequality ($t_{\text{pre}} \ll t_{\text{RR}}$) has received less attention because until now there were no explicit solutions for generic spin precession (unlike the Keplerian orbits that readily allowed orbit averaging in previous work). Our new solutions for spin precession allow us to fully exploit the timescale hierarchy of Eq. (1), expanding and detailing the ideas put forward in our previous paper [28]. We showed that spin precession is quasiperiodic implying that the relative orientations of the three angular momenta are fully specified by a single parameter, the magnitude of the total spin, that oscillates on the precession time. As is common in multi-timescale analyses, once the dynamics on the shorter time has been solved, the behavior of the system on the longer timescale can be studied as a quasiadiabatic process. We evolve our precessional solutions during the inspiral by double averaging the PN equations over both the orbital and the precessional timescales. Semianalytical precession-averaged inspirals turn out to be extremely efficient and can be carried out from infinitely large separation with negligible computational cost.

While our focus in this work is on spin precession, our study benefits from several recent investigations which also used separation of timescales to efficiently and accurately approximate both the dynamics and the associated GW signal. A series of papers by Klein *et al.* [26,44,45] used a multiscale analysis to construct semianalytic approximations to the frequency-domain waveforms for generic two-spin precessing binaries. Lundgren and O’Shaughnessy [46] used this timescale hierarchy to construct semianalytic approximations to the inspiral of precessing binaries with a single significant spin. The GWs emitted during the full inspiral-merger-ringdown of spinning, precessing binaries were also investigated using phenomenological models based on a single “effective spin” approximation [47–49] and the effective-one-body framework [50].

This paper is organized as follows. In Sec. II we derive explicit solutions for generic BBH spin precession at 2PN order on timescales short compared to the radiation-reaction time t_{RR} . These solutions allow spin precession to be classified into three different morphologies characterized by the qualitative behavior of the angle between the components of the two spins in the orbital plane. In Sec. III, we use our new solutions to precession average the radiation reaction on the binary at 1PN order and demonstrate how this precession averaging improves the computational efficiency with which GW-induced inspirals can be calculated compared to previous approaches relying solely on orbit averaging. Precession-averaged evolution does not preserve the memory of the initial precessional phase, just like orbit-averaged PN evolutions do not track the orbital phase. Section IV explores phase transitions between the three precessional morphologies, which are readily identified using our new formalism and have potentially interesting observational consequences. Finally, we conclude in Sec. V, highlighting the relevance of our new PN approach to both the theoretical understanding of BBHs and observational GW astronomy. We mainly focus on the relative orientation of the momenta; the evolution of the global orientation of the system will be addressed elsewhere [51]. Throughout the paper, we use geometrical units ($G = c = 1$) and write vectors in boldface, denoting the corresponding unit vectors by hats and their magnitude as (e.g.) $L = |\mathbf{L}|$. Latin subscripts ($i = 1, 2$) label the BHs in the binary. Binaries are studied at separations $r \geq 10M$, taken as a simple but *ad hoc* threshold for the breakdown of the PN approximation [52–54]. Animated versions of some figures are available online at the URLs listed in Ref. [55].

II. ANALYTIC SOLUTIONS ON THE PRECESSIONAL TIMESCALE

In this section we focus on the binary dynamics on the precessional time. Angular momentum conservation (Sec. II A) and the existence of a further constant of motion (Sec. II B) provide a simple parametrization of the binary dynamics through the identification of effective potentials. Solutions are classified according to the precession geometry (Sec. II C) and eventually expressed in an inertial frame (Sec. II D).

A. Parametrization of precessional dynamics

Let us consider BBHs on a circular orbit.¹ Let m_1 and m_2 denote the BBH masses, in terms of which we can define

¹Our approach can be readily generalized to nonzero eccentricity without complicating the geometry since the orbital pericenter precesses on a shorter timescale than the BBH spins do. We restrict our attention to circular orbits since radiation reaction is expected to suppress the eccentricity at large separations for most astrophysical systems [18,19].

the mass ratio $q = m_2/m_1 \leq 1$, the total mass $M = m_1 + m_2$, and the symmetric mass ratio $\eta = m_1 m_2 / M^2$. The spin magnitudes $S_i = m_i^2 \chi_i$ ($i = 1, 2$) are most conveniently parametrized in terms of the dimensionless Kerr parameter $0 \leq \chi_i \leq 1$, while the magnitude of the orbital angular momentum is related to the binary separation r through the Newtonian expression $L = \eta(rM^3)^{1/2}$.

The three angular momenta \mathbf{L} , \mathbf{S}_1 and \mathbf{S}_2 in principle constitute a nine-dimensional parameter space. However, there exist numerous constraints on the evolution of these parameters, greatly reducing the number of degrees of freedom. At the PN order considered here, the magnitudes of both spins are conserved throughout the inspiral (see e.g. Ref. [52]), reducing the number of degrees of freedom from nine to seven. The magnitude of the orbital angular momentum is conserved on the precession time (although it shrinks on the radiation-reaction time), further reducing the number of degrees of freedom from seven to six. The total angular momentum $\mathbf{J} = \mathbf{L} + \mathbf{S}_1 + \mathbf{S}_2$ is also conserved on the precession time, reducing the number of degrees of freedom from six to three. As described in greater detail in the next subsection, the projected effective spin ξ [56,57] is also conserved by both the orbit-averaged spin-precession equations at 2PN and radiation reaction at 2.5PN order, providing a final constraint that reduces the system to just two degrees of freedom. In an appropriately chosen non-inertial reference frame precessing about \mathbf{J} , precessional motion associated with one of these degrees of freedom can be suppressed, implying that the relative orientations of the three angular momenta \mathbf{L} , \mathbf{S}_1 and \mathbf{S}_2 can be specified by just a single coordinate! We will provide an explicit analytic construction of this procedure in this and the following subsection.

We begin by introducing two alternative reference frames in which the relative orientations of the three angular momenta can be specified explicitly. As shown in the left panel of Fig. 1, one may choose the z' axis to lie along \mathbf{L} , the x' axis such that \mathbf{S}_1 lies in the $x'z'$ plane, and the y' axis to complete the orthonormal triad. In this frame only three independent coordinates are needed to describe the relative orientations of the angular momenta; we choose them to be the angles

$$\cos \theta_1 = \hat{\mathbf{S}}_1 \cdot \hat{\mathbf{L}}, \quad (2a)$$

$$\cos \theta_2 = \hat{\mathbf{S}}_2 \cdot \hat{\mathbf{L}}, \quad (2b)$$

$$\cos \Delta\Phi = \frac{\hat{\mathbf{S}}_1 \times \hat{\mathbf{L}}}{|\hat{\mathbf{S}}_1 \times \hat{\mathbf{L}}|} \cdot \frac{\hat{\mathbf{S}}_2 \times \hat{\mathbf{L}}}{|\hat{\mathbf{S}}_2 \times \hat{\mathbf{L}}|}, \quad (2c)$$

where the sign of $\Delta\Phi$ is given by (cf. Fig. 1)

$$\text{sgn} \Delta\Phi = \text{sgn} \{ \mathbf{L} \cdot [(\mathbf{S}_1 \times \mathbf{L}) \times (\mathbf{S}_2 \times \mathbf{L})] \}. \quad (2d)$$

FIG. 1. Reference frames used in this paper to study BBH spin precession. The angles θ_1 , θ_2 , $\Delta\Phi$, and θ_{12} are defined in a frame aligned with the orbital angular momentum \mathbf{L} (left panel). The binary dynamics can also be studied in a frame aligned with the total angular momentum \mathbf{J} (right panel). Once \mathbf{L} is taken to lie in the xz plane, its direction is specified by S through the angle θ_L . The angle φ' corresponds to rotations of \mathbf{S}_1 and \mathbf{S}_2 about the total spin \mathbf{S} . The two frames pictured here are not inertial because the direction of \mathbf{L} changes together with the spins to conserve \mathbf{J} . These angles are defined in Eqs. (2), (4) and (9).

The relative orientations of the three angular momenta can alternatively be specified in a frame aligned with the total angular momentum \mathbf{J} . For fixed values of L , S_1 , and S_2 , the allowed range for $J = |\mathbf{J}|$ is

$$J_{\min} \leq J \leq J_{\max} \quad (3a)$$

where

$$J_{\min} = \max(0, L - S_1 - S_2, |S_1 - S_2| - L), \quad (3b)$$

$$J_{\max} = L + S_1 + S_2. \quad (3c)$$

As shown in the right panel of Fig. 1, one can choose the z axis parallel to \mathbf{J} and the x axis such that \mathbf{L} lies in the xz plane:

$$\mathbf{J} = J\hat{\mathbf{z}} \quad \text{and} \quad \mathbf{L} = L \sin \theta_L \hat{\mathbf{x}} + L \cos \theta_L \hat{\mathbf{z}}. \quad (4)$$

The third unit vector $\hat{\mathbf{y}} = \hat{\mathbf{z}} \times \hat{\mathbf{x}}$ completes the orthonormal triad. The total spin $\mathbf{S} = \mathbf{S}_1 + \mathbf{S}_2 = \mathbf{J} - \mathbf{L}$ will also lie in the xz plane:

$$\mathbf{S} = -L \sin \theta_L \hat{\mathbf{x}} + (J - L \cos \theta_L) \hat{\mathbf{z}}, \quad (5)$$

implying

$$\cos \theta_L = \frac{J^2 + L^2 - S^2}{2JL}. \quad (6)$$

We can also define a unit vector

$$\hat{\mathbf{S}}_{\perp} = \frac{(J - L \cos \theta_L) \hat{\mathbf{x}} + L \sin \theta_L \hat{\mathbf{z}}}{S} \quad (7)$$

which also lies in the xz plane but is orthogonal to $\hat{\mathbf{S}}$.

While the magnitudes L and J of the orbital and total angular momenta are conserved on the precession timescale, the same is not true for the total-spin magnitude S , which oscillates within the range

$$S_{\min} \leq S \leq S_{\max}, \quad (8a)$$

where

$$S_{\min} = \max(|J - L|, |S_1 - S_2|), \quad (8b)$$

$$S_{\max} = \min(J + L, S_1 + S_2). \quad (8c)$$

S can be used as a generalized coordinate to specify the directions of the angular momenta \mathbf{J} , \mathbf{L} , and \mathbf{S} ; we can see from Eqs. (4)–(6) that it is the only coordinate needed to specify these directions in the xyz frame.

Specifying the directions of the individual spins \mathbf{S}_1 and \mathbf{S}_2 in the xyz frame requires an additional generalized coordinate, which can be chosen to be the angle φ' between $\hat{\mathbf{S}}_{\perp}$ in Eq. (7) and the projection of \mathbf{S}_1 into the plane spanned by $\hat{\mathbf{S}}_{\perp}$ and $\hat{\mathbf{y}}$, as shown in the right panel of Fig. 1. This angle corresponds to rotations of \mathbf{S}_1 and \mathbf{S}_2 about \mathbf{S} and is given analytically by

$$\cos \varphi' = \frac{\hat{\mathbf{S}}_1 \cdot \hat{\mathbf{S}}_{\perp}}{|\hat{\mathbf{S}}_1 \times \hat{\mathbf{S}}|}. \quad (9)$$

In terms of the two coordinates S and φ' varying on the precession timescale, the three angular momenta in the xyz frame are

$$\mathbf{L} = \frac{A_1 A_2}{2J} \hat{\mathbf{x}} + \frac{J^2 + L^2 - S^2}{2J} \hat{\mathbf{z}}, \quad (10a)$$

$$\begin{aligned} \mathbf{S}_1 &= \frac{S^2 + S_1^2 - S_2^2}{2S} \hat{\mathbf{S}} + \frac{A_3 A_4}{2S} (\cos \varphi' \hat{\mathbf{S}}_{\perp} + \sin \varphi' \hat{\mathbf{y}}) \\ &= \frac{1}{4JS^2} [-(S^2 + S_1^2 - S_2^2) A_1 A_2 \\ &\quad + (J^2 - L^2 + S^2) A_3 A_4 \cos \varphi'] \hat{\mathbf{x}} + \frac{1}{2S} A_3 A_4 \sin \varphi' \hat{\mathbf{y}} \\ &\quad + \frac{1}{4JS^2} [(S^2 + S_1^2 - S_2^2)(J^2 - L^2 + S^2) \\ &\quad + A_1 A_2 A_3 A_4 \cos \varphi'] \hat{\mathbf{z}}, \end{aligned} \quad (10b)$$

$$\begin{aligned} \mathbf{S}_2 &= \frac{S^2 + S_2^2 - S_1^2}{2S} \hat{\mathbf{S}} - \frac{A_3 A_4}{2S} (\cos \varphi' \hat{\mathbf{S}}_{\perp} + \sin \varphi' \hat{\mathbf{y}}) \\ &= -\frac{1}{4JS^2} [(S^2 + S_2^2 - S_1^2) A_1 A_2 \\ &\quad + (J^2 - L^2 + S^2) A_3 A_4 \cos \varphi'] \hat{\mathbf{x}} - \frac{1}{2S} A_3 A_4 \sin \varphi' \hat{\mathbf{y}} \\ &\quad + \frac{1}{4JS^2} [(S^2 + S_2^2 - S_1^2)(J^2 - L^2 + S^2) \\ &\quad - A_1 A_2 A_3 A_4 \cos \varphi'] \hat{\mathbf{z}}, \end{aligned} \quad (10c)$$

where we defined

$$A_1 \equiv [J^2 - (L - S)^2]^{1/2}, \quad (11a)$$

$$A_2 \equiv [(L + S)^2 - J^2]^{1/2}, \quad (11b)$$

$$A_3 \equiv [S^2 - (S_1 - S_2)^2]^{1/2}, \quad (11c)$$

$$A_4 \equiv [(S_1 + S_2)^2 - S^2]^{1/2}. \quad (11d)$$

All the A_i 's are real and non-negative in the ranges specified by Eqs. (3) and (8).

B. Effective potentials and resonances

As anticipated in the previous subsection, there is an additional conserved quantity that can be used to eliminate φ' and thereby specify \mathbf{L} , \mathbf{S}_1 , and \mathbf{S}_2 with the single generalized coordinate S . This quantity is the projected effective spin [56,57]

$$\xi \equiv M^{-2} [(1 + q) \mathbf{S}_1 + (1 + q^{-1}) \mathbf{S}_2] \cdot \hat{\mathbf{L}} \quad (12)$$

which is a constant of motion of the orbit-averaged spin-precession equations at 2PN order and is also conserved by radiation reaction at 2.5PN order. Using Eqs. (10a)–(10c), we can express ξ as a function of S and φ' :

$$\begin{aligned} \xi(S, \varphi') &= \{(J^2 - L^2 - S^2)[S^2(1 + q)^2 - (S_1^2 - S_2^2)(1 - q^2)] \\ &\quad - (1 - q^2) A_1 A_2 A_3 A_4 \cos \varphi'\} / (4q M^2 S^2 L). \end{aligned} \quad (13)$$

Conservation of ξ restricts binary evolution to one-dimensional curves $\xi(S, \varphi') = \xi$ in the $S\varphi'$ plane as shown in the right panel of Fig. 2. The simple dependence of $\xi(S, \varphi')$ on φ' motivates us to define two “effective potentials” [28] corresponding to the extreme cases $\cos \varphi' = \mp 1$ for which \mathbf{L} , \mathbf{S}_1 and \mathbf{S}_2 are all coplanar:

$$\begin{aligned} \xi_{\pm}(S) &= \{(J^2 - L^2 - S^2)[S^2(1 + q)^2 - (S_1^2 - S_2^2)(1 - q^2)] \\ &\quad \pm (1 - q^2) A_1 A_2 A_3 A_4\} / (4q M^2 S^2 L). \end{aligned} \quad (14)$$

At S_{\min} and S_{\max}

$$\xi_{-}(S_{\min}) = \xi_{+}(S_{\min}), \quad \xi_{-}(S_{\max}) = \xi_{+}(S_{\max}), \quad (15)$$

because one of the A_i 's defined in Eqs. (11a)–(11d) vanishes if $S = S_{\min}$ or $S = S_{\max}$. The functions $\xi_{\pm}(S)$ thus form a loop that encloses all allowed values of S and ξ , as shown in the left panel of Fig. 2. BBHs are constrained to evolve back and forth along horizontal line segments of constant ξ bounded by the two effective potentials $\xi_{\pm}(S)$. The turning points in the evolution of S are given by the solutions of $\xi_{\pm}(S) = \xi$, where the binary meets an effective potential. Once squared, the equation $\xi_{\pm}(S) = \xi$ reduces to the following cubic equation in S^2 :

$$\sigma_6 S^6 + \sigma_4 S^4 + \sigma_2 S^2 + \sigma_0 = 0, \quad (16a)$$

where

$$\sigma_6 = q(1+q)^2, \quad (16b)$$

$$\sigma_4 = (1+q)^2[-2J^2q + L^2(1+q^2) + 2LM^2\xi q + (1-q)(S_2^2 - qS_1^2)], \quad (16c)$$

$$\begin{aligned} \sigma_2 = & 2(1+q)^2(1-q)[J^2(qS_1^2 - S_2^2) \\ & - L^2(S_1^2 - qS_2^2)] + q(1+q)^2(J^2 - L^2)^2 \\ & - 2LM^2\xi q(1+q)[(1+q)(J^2 - L^2) \\ & + (1-q)(S_1^2 - S_2^2)] + 4L^2M^4\xi^2q^2, \end{aligned} \quad (16d)$$

$$\begin{aligned} \sigma_0 = & (1-q^2)[L^2(1-q^2)(S_1^2 - S_2^2)^2 \\ & - (1+q)(qS_1^2 - S_2^2)(J^2 - L^2)^2 \\ & + 2LM^2q\xi(S_1^2 - S_2^2)(J^2 - L^2)], \end{aligned} \quad (16e)$$

which admits at most three real solutions for $S > 0$. The number of solutions in the range allowed by Eqs. (8a)–(8c) must be even because the two effective potentials form a closed loop and the Jordan curve theorem requires the number of intersections between a continuous closed loop and a line to be even [58] (although these intersections can coincide at extrema). Since two is the largest even number less than three, the equation $\xi_{\pm}(S) = \xi$ will generally have two solutions which we denote by S_{\pm} ($S_- \leq S_+$).

The total-spin magnitude S will oscillate between S_- and S_+ implying that spin precession is regular or quasiperiodic (this will be shown explicitly in Sec. II D below). The motion of the spins is not fully periodic because in an inertial frame the basis vectors $\hat{\mathbf{x}}$ and $\hat{\mathbf{y}}$ will generally not precess about \mathbf{J} by a rational multiple of π radians in the time it takes S to complete a full cycle from S_- and S_+ and back again. The turning points $S = S_{\pm}$ lie on the effective potentials, implying from the definition $\cos \varphi' = \mp 1$ that all three vectors \mathbf{L} , \mathbf{S}_1 , and \mathbf{S}_2 are coplanar. The qualitative evolution of φ' is related to the nature of the turning points S_{\pm} . This is illustrated in Fig. 2, where horizontal lines in the effective-potential diagram (left panel) correspond to

FIG. 2 (color online). Left: Effective potentials $\xi_{\pm}(S)$ for BBHs with $q = 0.6$, $\chi_1 = \chi_2 = 1$, $r = 100M$, and $J = 2.34M^2$. Conservation of the projected effective spin ξ constrains the BBH spins to precess along horizontal lines bounded by the effective-potential curves. The horizontal dashed lines intersecting the effective potentials at S_{\min} and S_{\max} (marked by empty squares) divide BBH spin precession into three different morphological phases distinguished by whether the angle φ' defined by Eq. (9) oscillates about π (top orange region), circulates from 0 to 2π (middle grey region), or oscillates about 0 (bottom purple region). The effective potentials admit two extrema ξ_{\min} and ξ_{\max} (marked by empty triangles) corresponding to the spin-orbit resonances discovered in Ref. [37]. Right: Contours of constant $\xi(S, \varphi')$ given by Eq. (13) for the same binary parameters. As BBH spins precess along the horizontal dashed lines in the left panel, they move along the curves in the $S\varphi'$ plane in the right panel illustrating the three morphological phases.

contours of constant $\xi(S, \varphi')$, computed using Eq. (13) (right panel). Three different cases are possible.

- (1) Both turning points lie on ξ_+ :

$$\xi_+(S_+) = \xi_+(S_-) = \xi. \quad (17a)$$

φ' oscillates about π never reaching 0 (orange region in Fig. 2).

- (2) One turning point is on ξ_- and the other is on ξ_+ :

$$\xi_{\pm}(S_-) = \xi_{\mp}(S_+) = \xi. \quad (17b)$$

φ' monotonically circulates from $-\pi$ to π during each precession cycle (grey region in Fig. 2).

- (3) Both turning points lie on ξ_- :

$$\xi_-(S_+) = \xi_-(S_-) = \xi. \quad (17c)$$

φ' oscillates about 0 never reaching π (purple region in Fig. 2).

The boundaries between the three regions are given by those values of ξ at which one of the turning points S_{\pm} coincides with either S_{\min} or S_{\max} (dashed lines in Fig. 2). Note that $\xi(S_{\min})$ may be less or greater than $\xi(S_{\max})$ depending on the values of q, χ_i, r and J .

The two turning points are degenerate ($S_+ = S_-$) at the extrema ξ_{\min} and ξ_{\max} of the effective potentials. At these extrema the derivatives

$$\begin{aligned} \frac{d\xi_{\pm}}{dS} = \frac{1+q}{2qM^2S^3L} & \left\{ (1-q)(J^2 - L^2)(S_1^2 - S_2^2) - (1+q)S^4 \right. \\ & \pm \frac{1-q}{A_1A_2A_3A_4} [S^8 - (J^2 + L^2 + S_1^2 + S_2^2)S^6 \\ & + (J^2 + L^2)(S_1^2 - S_2^2)^2S^2 + (S_1^2 + S_2^2)(J^2 - L^2)^2S^2 \\ & \left. - (S_1^2 - S_2^2)^2(J^2 - L^2)^2] \right\} \end{aligned} \quad (18)$$

vanish and $S = S_- = S_+$ is constant. Since

$$\lim_{S \rightarrow S_{\min}} \frac{d\xi_+}{dS} \geq \lim_{S \rightarrow S_{\min}} \frac{d\xi_-}{dS}, \quad (19a)$$

$$\lim_{S \rightarrow S_{\max}} \frac{d\xi_+}{dS} \leq \lim_{S \rightarrow S_{\max}} \frac{d\xi_-}{dS}, \quad (19b)$$

and at most two turning points can exist, it follows that ξ_+ admits a single maximum in $[S_{\min}, S_{\max}]$ and ξ_- admits a single minimum in $[S_{\min}, S_{\max}]$. The effective potentials therefore have exactly two distinct extrema for each value of the constants J, r, q, χ_1 and χ_2 . As clarified below, these special configurations correspond to the spin-orbit resonances discovered by other means in Ref. [37].

The equal-mass limit $q \rightarrow 1$ corresponds to $\xi_+(S) = \xi_-(S)$ [cf. Eq. (14)] implying that S is constant for all values

of ξ [note that $\xi_{\pm}(S_{\min}) \neq \xi_{\pm}(S_{\max})$]. This fact was noted at least as early as 2008 by Racine [57] and it was recently exploited in numerical-relativity simulations [39,59], but the constancy of S is a peculiarity of the equal-mass case and does not hold for generic binaries.

C. Morphological classification

Although the evolution of φ' already provides a way to characterize the precessional dynamics (Fig. 2), a more intuitive understanding can be gained by switching back to the **L**-aligned frame illustrated in the left panel of Fig. 1. Substituting Eqs. (10) and (13) into Eq. (2), we can express the angles θ_1, θ_2 and $\Delta\Phi$ as functions of S, J and ξ . This yields the remarkably simple expressions [28]

$$\cos \theta_1 = \frac{1}{2(1-q)S_1} \left[\frac{J^2 - L^2 - S^2}{L} - \frac{2qM^2\xi}{1+q} \right], \quad (20a)$$

$$\cos \theta_2 = \frac{q}{2(1-q)S_2} \left[-\frac{J^2 - L^2 - S^2}{L} + \frac{2M^2\xi}{1+q} \right], \quad (20b)$$

$$\cos \Delta\Phi = \frac{\cos \theta_{12} - \cos \theta_1 \cos \theta_2}{\sin \theta_1 \sin \theta_2}, \quad (20c)$$

where the angle $\theta_{12} = \arccos \hat{\mathbf{S}}_1 \cdot \hat{\mathbf{S}}_2$ between the two spins can also be written in terms of S :

$$\cos \theta_{12} = \frac{S^2 - S_1^2 - S_2^2}{2S_1S_2}. \quad (20d)$$

Equations (20a)–(20d) parametrize double-spin binary precession using a single parameter S . Some examples of the evolution of these angles over a precessional cycle are given in Fig. 3. The evolution of θ_1 and θ_2 is monotonic as S evolves between its two turning points S_{\pm} ; over a full precessional cycle these angles oscillate between two extrema lying on the effective potentials (dotted curves in Fig. 3). The evolution of $\Delta\Phi$ can be classified into three morphological phases similar to that of φ' :

- (1) $\Delta\Phi$ oscillates about 0 (never reaching π) if

$$\Delta\Phi(S_-) = \Delta\Phi(S_+) = 0; \quad (21a)$$

- (2) $\Delta\Phi$ circulates through the full range $[-\pi, \pi]$ if

$$\Delta\Phi(S_{\pm}) = 0 \quad \text{and} \quad \Delta\Phi(S_{\mp}) = \pi; \quad (21b)$$

- (3) $\Delta\Phi$ oscillates about π (never reaching 0) if

$$\Delta\Phi(S_-) = \Delta\Phi(S_+) = \pi. \quad (21c)$$

FIG. 3 (color online). Analytical solutions given by Eq. (20) for the evolution of the angles θ_1 (top panel), θ_2 (middle panel), and $\Delta\Phi$ (bottom panel) during a precession cycle. The evolution of three binaries with $\xi = 0.25$ (blue), 0.3 (green) and 0.35 (red) is shown for $q = 0.8$, $\chi_1 = 1$, $\chi_2 = 0.8$, $r = 20M$ and $J = 1.29M^2$. The evolution of θ_1 and θ_2 is monotonic during each half of a precession cycle and is bounded by the dotted lines for which $\cos \varphi = \mp 1$ [these curves can be found by substituting $\xi_{\pm}(S)$ for ξ in Eq. (20)]. Three classes of solutions are possible and define the binary morphology: $\Delta\Phi$ can oscillate about 0 ($\xi = 0.25$), circulate ($\xi = 0.3$) or oscillate about π ($\xi = 0.35$). An animated version of this figure is available online at Ref. [55], where precession solutions are evolved on t_{RR} .

The evolution of $\Delta\Phi$ allows us to unambiguously categorize the precessional dynamics into the three different classes listed above. We refer to these classes as *morphologies* because of the different shapes traced out by the BBH spins over a precession cycle. We show some examples of how the allowed region inside the effective-potential loop is divided between these three morphologies in Fig. 4. BBHs in the two oscillating morphologies are adjacent to the extrema of the effective potentials (ξ_{\min} and ξ_{\max}), while circulating binaries (if present) fill the gap in between. Schnittman’s spin-orbit resonances [37] can be reinterpreted as the limits of the two oscillating morphologies when the “precessional amplitude” $S_+ - S_-$ goes to zero at ξ_{\min} and ξ_{\max} , much like how circular orbits are the limits of eccentric orbits as the amplitude of the radial oscillations goes to zero.

According to the criteria listed in Eqs. (21a)–(21c), boundaries between the three morphologies (shown by horizontal dashed lines in Fig. 4) occur at values of ξ where $\cos \Delta\Phi$ given by Eq. (20c) changes discontinuously at one of the turning points S_{\pm} along the effective-potential loop $\xi_{\pm}(S)$. We know that $\Delta\Phi$ is either 0 or π along $\xi_{\pm}(S)$ because \mathbf{L} , \mathbf{S}_1 , and \mathbf{S}_2 are coplanar when $\cos \varphi' = \pm 1$ (see Fig. 1). A discontinuity can only occur when the denominator of Eq. (20c) vanishes, i.e. where one of the spins is either aligned or antialigned with the orbital angular momentum ($\sin \theta_i = 0$). These discontinuities can only happen at the turning points S_{\pm} because of the monotonic evolution of θ_i during each half of the precession cycle, as shown in the top and middle panels of Fig. 3. The four contours $\cos \theta_i = \pm 1$ ($\sin \theta_i = 0$) are shown by dotted curves in Fig. 4; we see that a boundary between morphologies occurs whenever these curves are tangent to the effective-potential loop $\xi_{\pm}(S)$. These boundaries had previously been described as unstable resonances [37].

The geometrical constraints imposed by Eqs. (3a)–(3c) and (8a)–(8c) imply that some morphologies may not be allowed for given values of L, J, q, χ_1 , and χ_2 . Three qualitatively different scenarios can occur, exemplified by the three panels of Fig. 4:

- (1) *Left panel:* BBH spins precess in all three of the morphologies listed in Eqs. (21a)–(21c). Libration about the coplanar configuration $\Delta\Phi = 0$ occurs for values of ξ close to ξ_{\min} , libration about the $\Delta\Phi = \pi$ configuration is found near ξ_{\max} , and $\Delta\Phi$ circulates for intermediate values of ξ . Our analysis in Ref. [28] was restricted to this case.
- (2) *Middle panel:* $\Delta\Phi$ oscillates about π for ξ close to both ξ_{\min} and ξ_{\max} , with circulation still allowed for intermediate values of ξ .
- (3) *Right panel:* $\Delta\Phi$ oscillates about π for all values $\xi_{\min} < \xi < \xi_{\max}$ (circulation and oscillation about 0 are both forbidden).

To distinguish these scenarios, it is useful to examine the values of $\Delta\Phi$ on the effective-potential loop at the extrema

FIG. 4 (color online). Effective potentials $\xi_{\pm}(S)$ of Eq. (14) for values of L , J , S_1 , and S_2 leading to three different sets of spin morphologies. The loop formed by the two curves encloses all allowed configurations for the constants listed in the legends. As in the left panel of Fig. 2, empty squares mark the extrema of S (S_{\min} and S_{\max}), empty triangles mark the extrema of ξ (ξ_{\min} and ξ_{\max}), and conservation of ξ restricts the BBH spins to precess along horizontal lines between the turning points S_{\pm} . BBH spin precession can be classified into three different morphologies by the behavior of $\Delta\Phi$ during a precession cycle: oscillation about 0 (blue region), circulation from $-\pi$ to π (green region), or oscillation about π (red region). The dashed boundaries between these morphologies occur at values of ξ where the dotted curves $\cos\theta_i = \pm 1$ intersect the effective-potential loop, as shown by the empty circles. All three morphologies are present if one intersection occurs on $\xi_+(S)$ and a second occurs on $\xi_-(S)$ (left panel), oscillation of $\Delta\Phi$ about 0 is forbidden if two intersections occur on either $\xi_+(S)$ or $\xi_-(S)$ (middle panel), and only oscillations about π are allowed if there are no such intersections (right panel).

ξ_{\min} and ξ_{\max} . Although it is straightforward to evaluate $\Delta\Phi$ numerically at ξ_{\max} , one can gain more intuition by instead evaluating it at S_{\min} . The value of $\Delta\Phi$ is the same at these two points since the slope of the effective-potential loop $\xi_+(S)$ connecting them is positive while that of the $\cos\theta_i = \pm 1$ contours is negative (as can be seen in Fig. 4). The curves therefore cannot be tangent to each other implying that $\Delta\Phi$ must remain constant on this portion of the loop. Equation (8b) requires that S_{\min} equals the greater of $|J - L|$ and $|S_1 - S_2|$; in the former case \mathbf{L} and \mathbf{J} are antialigned, while in the latter case \mathbf{S}_1 and \mathbf{S}_2 are antialigned. In either case, the components of \mathbf{S}_1 and \mathbf{S}_2 perpendicular to \mathbf{L} are antialigned ($\Delta\Phi = \pi$). This implies that $\Delta\Phi$ will oscillate about π near ξ_{\max} for all values of J , L , S_1 , and S_2 (as can be seen in all three panels of Fig. 4).

The values of $\Delta\Phi$ on the effective-potential loop at ξ_{\min} and S_{\max} are also the same because the segment of the curve connecting them has a positive slope. Equation (8c) indicates that S_{\max} equals the lesser of $|J + L|$ and $|S_1 + S_2|$; in the former case \mathbf{L} and \mathbf{J} are antialigned, while in the latter case \mathbf{S}_1 and \mathbf{S}_2 are aligned. The former case again requires the components of \mathbf{S}_1 and \mathbf{S}_2 perpendicular to \mathbf{L} to be antialigned ($\Delta\Phi = \pi$) but now the latter case requires these components to be aligned ($\Delta\Phi = 0$). For values of J , L , S_1 , and S_2 for which this latter case applies, $\Delta\Phi$ will oscillate

about 0 near ξ_{\min} and we have determined that all three morphologies are possible, as shown in the left panel of Fig. 4.

To distinguish the remaining two scenarios (whether or not $\Delta\Phi$ circulates for intermediate values of ξ), we must examine the intersections of the $\cos\theta_i = \pm 1$ contours with the effective-potential loop $\xi_{\pm}(S)$. There can be either zero or two of such intersections. If no intersections occur, $\Delta\Phi$ remains equal to π around the entire loop just as it is at ξ_{\max} and only oscillations about this value are possible, as shown in the right panel of Fig. 4. If there are two intersections, they must happen on the two portions of the loop with negative slopes (the segment connecting S_{\min} and ξ_{\min} and the segment connecting S_{\max} and ξ_{\max}). If both intersections happen on the *same* segment, $\Delta\Phi$ switches from π to 0 and back again as one traverses the loop from ξ_{\max} to ξ_{\min} resulting in the introduction of a circulating phase before restoring oscillations about π near ξ_{\min} , as seen in the middle panel of Fig. 4. If the two intersections happen on *different* segments, $\Delta\Phi$ switches to 0 at the first turning point and then to π at the other leading to oscillations about 0 near ξ_{\min} , as seen previously in the left panel of Fig. 4.

To summarize, the number of allowed morphologies in the effective-potential diagrams of Fig. 4 depends on the magnitude of the total angular momentum J :

FIG. 5 (color online). The (J, ξ) parameter space for BBHs with different minimum allowed total angular momentum J_{\min} . BBH spin morphology is shown with different colors, as indicated in the legend. The extrema $\xi_{\min}(J)$ and $\xi_{\max}(J)$ of the effective potentials constitute the edges of the allowed regions and are marked by solid blue (red) curves for $\Delta\Phi = 0(\pi)$. Dashed lines mark the boundaries between the different morphologies. The parameters q, χ_1, χ_2 and r are chosen as in Fig. 4, whose panels can be thought of as vertical (constant J) “sections” of this figure (where we suppress the S dependence). The lowest allowed value of ξ occurs at $J = |L - S_1 - S_2|$ in all three panels. Three phases are present for each vertical section with $J > |L - S_1 - S_2|$. This condition may either cover the entire parameter space (left panel) or leave room for additional regions where vertical sections include two different phases in which $\Delta\Phi$ oscillates about π and a circulating phase in between (center panel) or only a single phase where the spins librate about $\Delta\Phi = \pi$ (right panel). An animated version of this figure evolving on the radiation-reaction time t_{RR} is available online [55].

- (1) All three phases are allowed if

$$J > S_1 + S_2 - L. \quad (22)$$

This condition implies $S_{\max} = S_1 + S_2$ and hence $\Delta\Phi(\xi_{\min}) = 0$ (Fig. 4, left panel).

- (2) For lower values of J such that

$$L - |S_1 - S_2| < J < S_1 + S_2 - L, \quad (23)$$

$\Delta\Phi$ will oscillate about π near ξ_{\min} and ξ_{\max} and circulate from $-\pi$ to π for intermediate values of ξ (Fig. 4, middle panel). The first inequality ensures that two (anti)aligned configurations ($\sin\theta_i = 0$) can be found, while the second prevents $\Delta\Phi = 0$.

- (3) Finally, for

$$J < \min(S_1 + S_2 - L, L - |S_1 - S_2|), \quad (24)$$

the condition $\sin\theta_i = 0$ cannot be satisfied and $\Delta\Phi$ must oscillate about π (Fig. 4, right panel).

Whether these conditions can be satisfied is determined by the limits on J given by Eqs. (3a)–(3c). In particular, $J_{\min} = L - S_1 - S_2$ is a sufficient but not necessary condition for all three morphologies to coexist, while $J_{\min} = 0$ is a necessary but not sufficient condition for the single-phase case. The three-phase case was considered in our paper [28]

and is the only allowed case at sufficiently large binary separations ($L > S_1 + S_2$).

The $J\xi$ plane shown in Fig. 5 shows all BBH spin configurations for fixed values of q, χ_1, χ_2 and r at once. Since J and ξ are constant on the precession time t_{pre} , the position of BBHs in this figure is fixed on this timescale. The effective-potential diagrams of Fig. 4 can be thought of as vertical sections of Fig. 5 at fixed J where the S direction has been expanded. Each panel of Fig. 5 refers to a different choice of J_{\min} from Eq. (3b). $\Delta\Phi$ can only oscillate about 0 if $J > |L - S_1 - S_2|$. From Eq. (12), the limit $J = |L - S_1 - S_2|$ corresponds to the lowest allowed value of ξ . For separations large enough that $L > S_1 + S_2$, this configuration also corresponds to J_{\min} in which case $\Delta\Phi$ can oscillate about 0 for all allowed values of J (Fig. 5, left panel). If L is sufficiently small to admit values of J such that $J < |L - S_1 - S_2|$, a new region of the parameter space where $\Delta\Phi = 0$ is forbidden appears at small J (middle and right panels of Fig. 5). If even lower values $J < |S_1 - S_2| - L$ can be reached (i.e., if $J_{\min} = 0$), the leftmost region of the $J\xi$ plane does not even allow a circulating phase (right panel of Fig. 5).

The center and right panels of Fig. 5 reveal that the regions for which $\Delta\Phi$ oscillates (shown in blue and red) are very small for $L < S_1 + S_2$. This follows from the fact that these small values of the orbital angular momentum can only be achieved in the PN regime ($r \gtrsim 10M$) for low mass ratios. Oscillation of $\Delta\Phi$ relies upon coupling between the

two BBH spins, and the spin \mathbf{S}_2 becomes increasingly ineffective at maintaining this coupling as $q \rightarrow 0$ (cf. Sec. IV B below for more details). Nonetheless, a small region of the parameter space is always occupied by librating binaries as ξ approaches the resonant values ξ_{\min} and ξ_{\max} . For each value of ξ (horizontal sections of Fig. 5), one $\Delta\Phi = 0$ resonance and one $\Delta\Phi = \pi$ resonance occur at the largest ($\Delta\Phi = 0$) and the lowest ($\Delta\Phi = \pi$) allowed values of J . The effective spin ξ is therefore a good parameter to identify the resonant solutions, as we pointed out in Ref. [41].

D. Time dependence

Although S fully parametrizes the precessional dynamics, time-dependent expressions may be useful as well. The BBH spins obey the 2PN precession equations [17,57,60,61]

$$\frac{d\mathbf{S}_1}{dt} = \frac{1}{2r^3} \left[(4 + 3q)\mathbf{L} - \frac{3qM^2\xi}{1+q}\hat{\mathbf{L}} + \mathbf{S}_2 \right] \times \mathbf{S}_1, \quad (25a)$$

$$\frac{d\mathbf{S}_2}{dt} = \frac{1}{2r^3} \left[\left(4 + \frac{3}{q}\right)\mathbf{L} - \frac{3M^2\xi}{1+q}\hat{\mathbf{L}} + \mathbf{S}_1 \right] \times \mathbf{S}_2, \quad (25b)$$

which include the quadrupole-monopole interaction computed in Ref. [57]. These equations are averaged over the binary's orbital period t_{orb} and describe the evolution of the spins on the precession timescale t_{pre} . Equations (25a) and (25b) imply that the orbit-averaged evolution of $S = |\mathbf{S}_1 + \mathbf{S}_2|$ is given by

$$\frac{dS}{dt} = -\frac{3(1-q^2)}{2q} \frac{S_1 S_2}{S} \frac{(\eta^2 M^3)^3}{L^5} \left(1 - \frac{\eta M^2 \xi}{L} \right) \times \sin \theta_1 \sin \theta_2 \sin \Delta\Phi. \quad (26)$$

Integrating Eq. (26) yields solutions $S(t)$, and that specifies \mathbf{L} , \mathbf{S}_1 , and \mathbf{S}_2 as functions of time through substitution into Eqs. (10a)–(10c). Some examples of $S(t)$ for different values of ξ are shown in the top panel of Fig. 6.

These time-dependent solutions confirm the scenario outlined in Sec. II B, with S oscillating between two turning points S_- and S_+ at which $dS/dt = 0$. At these turning points, the three angular momenta are coplanar [from Eq. (26), $dS/dt = 0$ implies either $\sin \Delta\Phi = 0$ or $\sin \theta_i = 0$] and the BBHs lie on the effective potentials $(\xi_{\pm}(S_{\pm}) = \xi)$. The spin-orbit resonances ξ_{\min} and ξ_{\max} are shown with dashed lines in Fig. 6 and correspond to the zero-amplitude limits of the generic oscillatory solutions. From Eq. (26), we can define the precessional period τ as the time needed to complete a full cycle in S ,

$$\tau(L, J, \xi) = 2 \int_{S_-}^{S_+} \frac{dS}{|dS/dt|}. \quad (27)$$

FIG. 6 (color online). Time-dependent solutions for the total-spin magnitude S (top panel) and the orbital-angular-momentum phase Φ_L (bottom panel). We set $q = 0.7$, $\chi_1 = 0.7$, $\chi_2 = 0.9$, $r = 30M$ and $J = 1.48M^2$ and integrate Eq. (26) for three values of ξ corresponding to the three different spin morphologies: $\Delta\Phi$ oscillates about 0 ($\xi = 0.17$, blue), circulates ($\xi = 0.25$, green), and oscillates about π ($\xi = 0.34$, red). Initial conditions have been chosen such that $S = S_-$ and $\Phi_L = 0$ at $t = 0$. The oscillations in S induce small wiggles in Φ_L on top of a mostly linear drift. Spin-orbit resonances (horizontal dashed lines, top panel) correspond to configurations for which S is constant and can be interpreted as zero-amplitude limits of generic oscillatory solutions. The projections of the effective potentials, i.e. parametric curves $[\tau(\xi)/2, S_+(\xi)]$ and $[\tau(\xi), S_-(\xi)]$, are shown with dotted lines. An animated version of this figure is available online [55].

The precession timescale $t_{\text{pre}} \sim (2\pi M/\eta)(r/M)^{5/2}$ provides an order-of-magnitude estimate for this exact precessional period. The period τ remains finite at the spin-orbit resonances ξ_{\min} and ξ_{\max} in much the same way that the period of a simple harmonic oscillator remains finite in the limit of small oscillations.

The time evolution of the three angular momenta \mathbf{L} , \mathbf{S}_1 and \mathbf{S}_2 is fully given by Eqs. (10a)–(10c) and (26) when described in the noninertial frames of Fig. 1. However, \mathbf{J} and \mathbf{L} will generally not be confined to a plane in an inertial frame. The direction of \mathbf{J} is fixed on the precession

timescale t_{pre} , and hence so is $\hat{\mathbf{z}}$. The two remaining basis vectors will precess about the z axis:

$$\frac{d\hat{\mathbf{x}}}{dt} = \Omega_z \hat{\mathbf{z}} \times \hat{\mathbf{x}} = \Omega_z \hat{\mathbf{y}}, \quad \frac{d\hat{\mathbf{y}}}{dt} = \Omega_z \hat{\mathbf{z}} \times \hat{\mathbf{y}} = -\Omega_z \hat{\mathbf{x}}. \quad (28)$$

The solution to these two equations gives $\hat{\mathbf{x}}(t)$ and $\hat{\mathbf{y}}(t)$ and hence $\mathbf{L}(t)$, $\mathbf{S}_1(t)$, and $\mathbf{S}_2(t)$ in an inertial frame from Eqs. (10a)–(10c) and (13). The orbital angular momentum \mathbf{L} precesses about \mathbf{J} with frequency Ω_z given by [28]

$$\Omega_z = \frac{J}{2} \left(\frac{\eta^2 M^3}{L^2} \right)^3 \left\{ 1 + \frac{3}{2\eta} \left(1 - \frac{\eta M^2 \xi}{L} \right) - \frac{3(1+q)}{2qA_1^2 A_2^2} \left(1 - \frac{\eta M^2 \xi}{L} \right) [4(1-q)L^2(S_1^2 - S_2^2) - (1+q)(J^2 - L^2 - S^2)(J^2 - L^2 - S^2 - 4\eta M^2 L \xi)] \right\}. \quad (29)$$

This equation can be derived by substituting Eqs. (25a)–(25b) and (28) into the time derivative of Eq. (5). For concreteness, let us specify an inertial frame such that \mathbf{L} lies in the xz plane at $S = S_-$. At the point on a precession cycle specified by the total-spin magnitude S , the direction of \mathbf{L} is specified by the polar angles θ_L from Eq. (6) and the azimuthal angle

$$\Phi_L = \begin{cases} \int_{S_-}^S \Omega_z \frac{dS}{|dS/dt|} & \text{for } S: S_- \rightarrow S_+ \\ \frac{\alpha}{2} + \int_S^{S_+} \Omega_z \frac{dS}{|dS/dt|} & \text{for } S: S_+ \rightarrow S_- \end{cases} \quad (30)$$

where the two cases refer to the first and the second half of the precession cycle, and

$$\alpha(L, J, \xi) = 2 \int_{S_-}^{S_+} \Omega_z \frac{dS}{|dS/dt|} \quad (31)$$

is the total change in the azimuthal angle Φ_L over a full precession cycle. Solutions $\Phi_L(t)$ are shown in the bottom panel of Fig. 6. The angle Φ_L mainly exhibits a linear drift due to the leading-PN-order term in Eqs. (25a)–(25b). Spin-spin couplings are of higher PN order and cause small wiggles on top of this linear drift. Binaries in spin-orbit resonances (ξ_{\min} and ξ_{\max}) precess at a constant rate Ω_z with all three vectors \mathbf{L} , \mathbf{S}_1 , and \mathbf{S}_2 jointly precessing about \mathbf{J} . Just as $\Delta\Phi$ is ill defined if either of the \mathbf{S}_i is aligned with \mathbf{L} ($\cos\theta_i = \pm 1$), Φ_L and thus α is ill defined if \mathbf{L} is aligned with \mathbf{J} ($\cos\theta_L = \pm 1$). This occurs for values of J and ξ for which $S_- = S_{\min} = |J - L|$ or $S_+ = S_{\max} = J + L$, corresponding to some of the transitions between the different classes of the evolution of φ' (dashed lines in Fig. 2).

We stress here that the time-dependent expressions reported in this section are only valid on times $t \sim \tau \ll t_{\text{RR}}$, i.e. when the precessional dynamics approximately decouples from the inspiral. This approximation breaks down at small separations, where the difference between the three timescales is smaller (cf. Sec. III C).

III. PRECESSION-AVERAGED EVOLUTION ON THE INSPIRAL TIMESCALE

The previous section focused on spin dynamics on the precessional timescale. We now consider how spin precession evolves as BBHs inspiral due to radiation reaction. Our main tool is a precession-averaged equation to model the binary inspiral (derived in Sec. III A below) that will allow us to overcome numerical limitations of our previous analyses [35,36,38,40,41] and evolve BBHs inwards from arbitrarily large separations (Sec. III B). This improved computational scheme relying on our new multi-scale analysis allows us to more efficiently “transfer” BBHs from the large separations where they form astrophysically down to the small separations relevant for GW detection. In Sec. III C we compare the results of our precession-averaged evolution against the standard integration of the merely orbit-averaged spin-precession equations.

A. Averaging the average

In the usual PN formulation (see e.g. Ref. [17]), the timescale hierarchy $t_{\text{orb}} \ll t_{\text{pre}} \ll t_{\text{RR}}$ is exploited to average the evolution equations for \mathbf{L} , \mathbf{S}_1 , and \mathbf{S}_2 over the orbital period T . We already saw above how this orbit averaging can be used to increase the computational efficiency with which spin precession can be calculated [Eqs. (25a)–(25b) can be integrated with time steps $t_{\text{orb}} \ll \Delta t \ll t_{\text{pre}}$ much longer than the orbital timescale]. Radiation reaction can be similarly orbit averaged:

$$\left\langle \frac{d\mathbf{L}_{\text{RR}}}{dt} \right\rangle_{\text{orb}} = \frac{1}{T} \int_0^{2\pi} \frac{d\mathbf{L}_{\text{RR}}}{dt} \frac{d\psi}{d\psi/dt}, \quad (32)$$

where $d\mathbf{L}_{\text{RR}}/dt$ is the instantaneous change in the orbital angular momentum due to GW radiation reaction and ψ is the true anomaly parametrizing the orbital motion. The flux $d\mathbf{L}_{\text{RR}}/dt$ depends implicitly on both ψ and the angular momenta \mathbf{L} , \mathbf{S}_1 , and \mathbf{S}_2 ; the former dependence can be averaged over since we have analytic solutions to the orbital motion as function of ψ , while the angular momenta may be held fixed, since they barely evolve over an orbital period. Spin precession may be calculated on the radiation-reaction timescale by numerically integrating the coupled system of ordinary differential equations (ODEs) given by Eqs. (25a)–(25b) and (32) with the time step Δt given above.

We derived analytic solutions to the orbit-averaged spin-precession equations (25a)–(25b) in Sec. II that depend on

the magnitudes L and J that evolve on the radiation-reaction timescale t_{RR} . In a similar spirit to the orbit averaging discussed above, we can use these solutions to *precession average* the evolution equations for L and J . We define the precession average of some scalar quantity X to be

$$\langle X \rangle_{\text{pre}} \equiv \frac{2}{\tau} \int_{S_-}^{S_+} \langle X \rangle_{\text{orb}} \frac{dS}{|dS/dt|} \quad (33)$$

where dS/dt is given as a function of S in Eq. (26). We can hold L , J , and ξ fixed on the right-hand side of this equation because they barely evolve during a precession cycle, much as we held the vectorial angular momenta fixed in the orbit averaging since they evolve on the longer timescale $t_{\text{pre}} \gg t_{\text{orb}}$.

Since ξ is conserved by radiation reaction at 2.5PN order [56,57], we need only find precession-averaged evolution equations for L and J to evolve our spin-precession solutions on the radiation-reaction timescale t_{RR} . Since $L^2 = \mathbf{L} \cdot \mathbf{L}$, $dL/dt = \hat{\mathbf{L}} \cdot d\mathbf{L}_{\text{RR}}/dt$ and the precession-averaged evolution of L is given by

$$\left\langle \frac{dL}{dt} \right\rangle_{\text{pre}} = \frac{2}{\tau} \int_{S_-}^{S_+} \hat{\mathbf{L}} \cdot \left\langle \frac{d\mathbf{L}_{\text{RR}}}{dt} \right\rangle_{\text{orb}} \frac{dS}{|dS/dt|}. \quad (34)$$

We similarly have $dJ/dt = \hat{\mathbf{J}} \cdot d\mathbf{J}_{\text{RR}}/dt$, but since $\mathbf{J} = \mathbf{L} + \mathbf{S}_1 + \mathbf{S}_2$ and GW emission does not directly affect the individual spins ($d\mathbf{S}_{i,\text{RR}}/dt = 0$), $d\mathbf{J}_{\text{RR}}/dt = d\mathbf{L}_{\text{RR}}/dt$ and we have

$$\left\langle \frac{dJ}{dt} \right\rangle_{\text{pre}} = \frac{2}{\tau} \int_{S_-}^{S_+} \hat{\mathbf{J}} \cdot \left\langle \frac{d\mathbf{L}_{\text{RR}}}{dt} \right\rangle_{\text{orb}} \frac{dS}{|dS/dt|}. \quad (35)$$

The orbit-averaged angular momentum flux $\langle d\mathbf{L}_{\text{RR}}/dt \rangle_{\text{orb}}$ up to 1PN is given by [17]

$$\begin{aligned} \left\langle \frac{d\mathbf{L}_{\text{RR}}}{dt} \right\rangle_{\text{orb}} &= -\frac{32\eta L}{5M} \left(\frac{M}{r} \right)^4 \\ &\times \left[\left(1 - \frac{2423 + 588\eta M}{336r} \right) \hat{\mathbf{L}} + \mathcal{O}\left(\frac{M}{r} \right)^{3/2} \right]. \end{aligned} \quad (36)$$

Note that this expression is parallel to $\hat{\mathbf{L}}$ and independent of S . Substituting this result into Eq. (35) yields

$$\left\langle \frac{dJ}{dt} \right\rangle_{\text{pre}} = \frac{2}{\tau} \int_{S_-}^{S_+} \hat{\mathbf{L}} \cdot \left\langle \frac{d\mathbf{L}_{\text{RR}}}{dt} \right\rangle_{\text{orb}} \cos \theta_L \frac{dS}{|dS/dt|}, \quad (37)$$

where we used Eq. (4), and $\cos \theta_L$ is given in Eq. (6) as a function of S . Finally, Eqs. (34) and (37) together lead to

$$\left\langle \frac{dJ}{dL} \right\rangle_{\text{pre}} = \frac{1}{2LJ} (J^2 + L^2 - \langle S^2 \rangle_{\text{pre}}), \quad (38)$$

which reduces the computation of BBH spin precession on the radiation-reaction timescale to solving a single ODE [28]! Equation (38) is independent of the details of spin precession (which are encoded in $\langle S^2 \rangle_{\text{pre}}$) and is also independent of the PN expansion for $\langle d\mathbf{L}_{\text{RR}}/dt \rangle_{\text{orb}}$ provided this is parallel to $\hat{\mathbf{L}}$ and independent of S . As shown in Eq. (36), both of these conditions are satisfied at the 1PN level but break down at higher PN order. We address the range of validity of our approach in Sec. III C, where we also perform extensive comparisons with full integrations of the conventional orbit-averaged equations.

Examples of solutions to Eq. (38) are shown in Fig. 7, where J is evolved from $r = 10^9 M$ to $r = 10M$. Solutions $J(r)$ are bounded at all separations by the spin-orbit resonances ξ_{min} and ξ_{max} which extremize the magnitude J for each fixed ξ (cf. Sec. II C and Fig. 5). We perform ODE integrations using the LSODA algorithm [62] as wrapped by the PYTHON module SCIPY [63]; integrations of Eq. (38) are numerically feasible for arbitrary values of $q < 1$, $\chi_1 \leq 1$, $\chi_2 \leq 1$, and *arbitrarily* large initial separation.

Our solutions to the spin-precession equations also depend on the direction $\hat{\mathbf{J}}$, since this defines the z axis in the orthonormal frame of Fig. 1. The precession-averaged evolution of this direction is

$$\left\langle \frac{d\hat{\mathbf{J}}}{dt} \right\rangle_{\text{pre}} = \frac{1}{J} \left\langle \left\langle \frac{d\mathbf{L}_{\text{RR}}}{dt} \right\rangle_{\text{orb}} - \frac{dJ}{dt} \hat{\mathbf{J}} \right\rangle_{\text{pre}} \quad (39)$$

which is proportional to the precession average of the total angular momentum radiated perpendicular to $\hat{\mathbf{J}}$. Although the vector given by the right-hand side of Eq. (39) will generally not vanish over a single precession cycle, if the angle α given by Eq. (31) above is not an integer multiple of 2π this vector will precess about $\hat{\mathbf{J}}$ in an inertial frame. This implies that $\hat{\mathbf{J}}$ will precess in a narrow cone in an inertial frame on the radiation-reaction timescale remaining approximately constant [16,64]. As shown for some of the binaries of Fig. 7, the condition $\alpha = 2\pi n$ for integer n is indeed satisfied in generic inspirals at meaningful separations. Preliminary results indicate that interesting spin dynamics arises at these newly identified resonances [51]. In this paper, we restrict our attention to the relative orientations of the three angular momenta as specified by the three angles in Eqs. (20a)–(20c).

B. The large-separation limit

We can gain additional physical insight by examining Eq. (38) in the large-separation limit $L/M^2 \rightarrow \infty$. Let us define

FIG. 7 (color online). Evolution of the total angular momentum magnitude J during the inspiral. Three binary configurations are considered here: $\xi = -0.5$ (orange), 0 (purple) and 0.5 (green) for $q = 0.4$, $\chi_1 = 0.9$, $\chi_2 = 0.8$. Equation (38) is solved for several different initial conditions (solid lines, sequential colors) as the separation r and the angular momentum $L = \eta(rM^3)^{1/2}$ decrease. Solutions are bounded at all separations by the spin-orbit resonances (dotted lines) which extremize the allowed value of J for fixed ξ . Two of the binaries pictured here cross one of the resonant conditions $\alpha = 2\pi n$ (empty circles) where changes in the direction $\hat{\mathbf{J}}$ are expected. The inset shows the same evolutions for a wider separation range.

$$\kappa \equiv \frac{J^2 - L^2}{2L}, \quad (40)$$

such that Eq. (38) becomes

$$\frac{d\kappa}{dL} = -\frac{\langle S^2 \rangle_{\text{pre}}}{2L^2}. \quad (41)$$

The right-hand side vanishes at large separations where $S \ll L$, implying that

$$\kappa_\infty \equiv \lim_{r/M \rightarrow \infty} \kappa \quad (42)$$

is constant. This implies that κ provides a more convenient label for precessing BBHs at large separations because it asymptotes to a constant while J diverges. At large separations J evolves as

$$J = \sqrt{L(2\kappa + L)} \approx \sqrt{L(2\kappa_\infty + L)}, \quad (43)$$

as illustrated in the inset of Fig. 7. From Eq. (40) and $\mathbf{J} = \mathbf{L} + \mathbf{S}$ one also obtains

$$\kappa_\infty = \lim_{r/M \rightarrow \infty} \mathbf{S} \cdot \hat{\mathbf{L}} \quad (44)$$

implying that κ asymptotes to the projection of the total spin onto the orbital angular momentum. The constant κ_∞ can be calculated for a binary at finite separation by integrating $d\kappa/dL$ all the way to $r/M \rightarrow \infty$. This integration can be performed by defining $u = 1/2L$ such that $d\kappa/du = \langle S^2 \rangle_{\text{pre}}$ can be integrated over a compact domain.

The two constants κ_∞ and ξ are linear combinations of the asymptotic values of the inner products $\hat{\mathbf{S}}_i \cdot \hat{\mathbf{L}}$ defined in Eqs. (20a)–(20d) in the large-separation limit. The constancy of these inner products at large separations is also apparent from Eqs. (25a)–(25b), where the \mathbf{S}_i will precess about \mathbf{L} when spin-orbit coupling dominates over spin-spin coupling. From Eqs. (12) and (44) one finds

$$\cos \theta_{1\infty} \equiv \lim_{r/M \rightarrow \infty} \hat{\mathbf{S}}_1 \cdot \hat{\mathbf{L}} = \frac{-M^2 \xi + \kappa_\infty (1 + q^{-1})}{S_1 (q^{-1} - q)}, \quad (45a)$$

$$\cos \theta_{2\infty} \equiv \lim_{r/M \rightarrow \infty} \hat{\mathbf{S}}_2 \cdot \hat{\mathbf{L}} = \frac{M^2 \xi - \kappa_\infty (1 + q)}{S_2 (q^{-1} - q)}. \quad (45b)$$

The terms in Eqs. (20a)–(20d) proportional to S^2 become increasingly significant at smaller separations and induce oscillations in θ_i on the precession timescale, while the breakdown of the asymptotic approximation to $J(L)$ given in Eq. (43) causes J (and hence θ_i) to deviate on the radiation-reaction timescale for BBHs with different values of ξ , as seen in Fig. 7. The constraints $|\cos \theta_{1\infty}| \leq 1$ and $|\cos \theta_{2\infty}| \leq 1$ define the physically allowed values of ξ and κ_∞ . These parameters, or equivalently $\theta_{1\infty}$ and $\theta_{2\infty}$, can be used to identify an entire BBH inspiral (as far as the relative orientation of the angular momenta is concerned) without reference to a particular separation or frequency, as typically done in GW applications [23–25, 41, 65, 66].

C. Efficient binary transfer

Our new precession-averaged equation for dJ/dL [Eq. (38)] can be used to efficiently “transfer” BBHs from the large separations at which they form astrophysically to the smaller separations at which the GWs they emit become detectable. This equation can be integrated with a time step $t_{\text{pre}} \ll \Delta t' \ll t_{\text{RR}}$ much longer than the time step $t_{\text{orb}} \ll \Delta t \ll t_{\text{pre}}$ on which merely orbit-averaged equations must be integrated. This greater efficiency comes at the cost of no longer being able to keep track of the precessional phase, in much the same way that orbit-averaged equations do not explicitly evolve the orbital phase. This is not a major problem for population-synthesis studies however, because

evolution over a timescale $\Delta t'$ will randomize the precessional phase, as described below. If one needs to track the precessional phase below a certain separation (such as that corresponding to the lowest detectable GW frequencies) one can randomly initialize the phase at this separation and then employ orbit-averaged equations. The following procedure explicitly outlines how to evolve the spin orientations of a population of BBHs from large to small separations.

- (1) Given a sample of BBHs specified by values of q , χ_1 and χ_2 , choose a distribution $p_i(\theta_1, \theta_2, \Delta\Phi)$ for the angles that describes the spin orientations at an initial separation r_i . This initial distribution is determined by the interactions between BHs and their astrophysical environment that lead to binary formation (cf. Refs. [40,67–69] on stellar-mass BHs and Refs. [70–74] on supermassive BBHs).
- (2) Rewrite this initial distribution as a distribution $p_i(J, \xi)$ using the relations

$$S = [S_1^2 + S_2^2 + 2S_1S_2(\sin\theta_1 \sin\theta_2 \cos\Delta\Phi + \cos\theta_1 \cos\theta_2)]^{1/2}, \quad (46a)$$

$$J = [L^2 + S^2 + 2L(S_1 \cos\theta_1 + S_2 \cos\theta_2)]^{1/2}, \quad (46b)$$

$$\xi = \frac{qS_1 \cos\theta_1 + S_2 \cos\theta_2}{\eta M^2(1+q)}. \quad (46c)$$

- (3) Evolve each member of the distribution $p_i(J, \xi)$ to a smaller separation r_f using Eq. (38) for dJ/dL (ξ remains constant). This yields a final distribution $p_f(J, \xi)$.
- (4) For each member of the distribution $p_f(J, \xi)$, create a distribution of values of S in the range $S_-(J, \xi) \leq S \leq S_+(J, \xi)$ weighted by $(dS/dt)^{-1}$ given by Eq. (26). BBHs spend less time at values of S where the “velocity” dS/dt is large. This yields a distribution $p_f(S, J, \xi)$.
- (5) Convert $p_f(S, J, \xi)$ into a distribution of final angles $p_f(\theta_1, \theta_2, \Delta\Phi)$ using Eqs. (20a)–(20d) and a randomly chosen sign for $\Delta\Phi$.

Examples of this binary transfer are given in Fig. 8 for three different initial spin distributions.

- (1) *Isotropic sample* (top panels): Both spin vectors are isotropically distributed (flat uncorrelated distributions in $\cos\theta_1$, $\cos\theta_2$ and $\Delta\Phi$).
- (2) *One aligned BH* (middle panels): One BH spin (either the spin of the primary or the spin of the secondary) is aligned within 10° of the orbital angular momentum, while the other spin angle θ_i has a flat distribution in $[0^\circ, 180^\circ]$; $\Delta\Phi$ is also flat in $[-180^\circ, 180^\circ]$.

- (3) *Gaussian spikes* (bottom panels): θ_1 and θ_2 have Gaussian distributions peaked at 45° and 135° with deviations of 10° ; $\Delta\Phi$ is kept flat in $[-180^\circ, 180^\circ]$.

We evolve these distributions from $r_i = 1000M$ to $r_f = 10M$ and show marginalized distributions of the three angles θ_1 , θ_2 , and $\Delta\Phi$ at several intermediate separations. An animated version of this figure can be found online [55]. The isotropic sample remains isotropic, as found previously using the orbit-averaged equations [73]. A greater fraction of the BBHs in the distribution with one aligned BH undergo a phase transition from a circulating to a librating morphology, as described in Sec. IV below and also found in previous studies with the orbit-averaged equations [40]. If the angles θ_i initially have Gaussian distributions, these Gaussians will spread out as the inspiral proceeds.

We use the BBH inspirals from $r_i = 1000M$ to $r_f = 10M$ shown in Fig. 8 to compare the efficiency of our new precession-averaged approach to the integration of the standard—i.e., orbit-averaged—PN equations. In the standard approach, one must numerically integrate ten coupled ODEs specifying the directions of the three angular momenta and the magnitude of the orbital velocity; we use the PN equations quoted by Refs. [35,36]. We implement the same 2PN spin-precession equations² given by Eqs. (25a)–(25b) but include radiation reaction up to 3.5PN order, as in Eq. (2.6) of Ref. [36]. Integrations are performed using the same algorithm specified above [62,63]. The agreement between the two approaches is seen to be excellent up to $r \sim 50M$, and minor discrepancies emerge at smaller separations.

Two approximations made in the precession-averaged approach may explain these discrepancies. While ξ is held constant throughout the inspiral in the precession-averaged approach (consistent with 2.5PN radiation reaction), conservation of ξ is not enforced in the orbit-averaged approach, which employs 3.5PN radiation reaction. The largest deviations $\Delta\xi$ in the latter approach are of the order 10^{-10} ; ξ is effectively constant in the PN regime ($r \gtrsim 10M$). Numerical-relativity simulations may be used to test conservation of ξ at smaller separations. We have verified that additional PN corrections in Eq. (36), implemented in our orbit-average code up to 3.5PN, introduce very mild corrections to the evolution of J : the largest variations observed in our evolutions are of order $\Delta J \sim 10^{-2}$.

The second and less reliable approximation involves the timescale hierarchy itself. The precession time $t_{\text{pre}} \sim (r/M)^{5/2}$ and radiation-reaction time $t_{\text{RR}} \sim (r/M)^4$ become more comparable at lower separations, reducing the effectiveness of our quasiadiabatic approach. The precession-averaging procedure defined in Eq. (33) assumes that quantities like L and J varying on t_{RR} remain

²Higher-order PN corrections to the spin-precession equations have been computed in Refs. [75–77]; their implementation is left to future work.

FIG. 8 (color online). Precession-averaged BBH inspirals as described in Sec. III C (purple/darker) compared to numerical integration of the orbit-averaged PN equations [35,36] (orange/lighter). Marginalized distributions of the spin angles θ_1 , θ_2 , and $|\Delta\Phi|$ (rows) are shown at several separations along the inspirals [columns: $r_i = 1000M$, $500M$, $100M$, $50M$, and $10M$]. The three initial spin distributions are isotropic (top panels), one aligned BH (middle panels), and Gaussian spikes (bottom panels) as described in Sec. III C. The two approaches are in good agreement except for minor deviations in the distribution of $\Delta\Phi$ at $r \sim 10M$. We take $q = 0.7$, $\chi_1 = 0.8$ and $\chi_2 = 0.4$ for all BBHs. An animated version of this figure is available online [55].

constant over a full precession cycle τ , but this assumption will break down as the timescale hierarchy becomes invalid.

Figure 8 shows that differences between the two approaches are most pronounced in $p_r(\Delta\Phi)$. This variable is the most sensitive to the precessional dynamics; predictions for the angles θ_1 and θ_2 remain reasonably accurate even at $r \sim 10M$. The differences seem to average out for wider distributions (top panels) but become more evident for more compact initial distributions (bottom panels). Averaging over the precessional dynamics prevents us from tracking the precession phase, implying that the two approaches will make different predictions for quantities (like S and $\Delta\Phi$) varying on the precession timescale when the initial separation is sufficiently small that memory of the initial phases has not been fully forgotten. Predictions of physical quantities varying on the radiation-reaction timescale (like J and the precession morphology) will remain robust down to small separations, as explored in Secs. IV B and IV C below.

We compare the computational efficiency of the precession- and orbit-averaged approaches in Fig. 9. Isotropic samples of 100 BBHs are transferred from large initial separations r_i to a final separation $r_f = 10M$. The CPU time required by the two approaches scales differently with the initial separation. The orbit-averaged (OA) equations must be integrated with a time step shorter than the precession time, implying that the total number of time steps scales as

$$N_{\text{OA}} \propto \int_{r_f}^{r_i} \frac{dr}{\dot{r}_{\text{GW}} t_{\text{pre}}} \sim r_i^{3/2}, \quad (47)$$

where $\dot{r}_{\text{GW}} \propto r^{-3}$ as given by the quadrupole formula [18,19]. The ratio $t_{\text{RR}}/t_{\text{pre}} \propto r^{3/2}$ increases dramatically at large separations leading to a corresponding increase in the computational cost. In the precession-averaged (PA) approach, the integration of dJ/dL in Eq. (38) only requires time steps proportional to L , hence

$$N_{\text{PA}} \propto \int_{L_f}^{L_i} \frac{dL}{L} \sim \log(L_i) \propto \log(r_i). \quad (48)$$

The precession-averaged approach is very efficient at large separations because the solutions to Eq. (38) become very smooth in this limit as seen from Eq. (43) and Fig. 7. Precession-averaged inspirals may even be computed from infinite separations through a change of variables to $u \equiv (2L)^{-1}$. The integrator spends most of the computational time at small separations, where spin effects—notably the numerical evaluation of S_{\pm} —need to be tracked with high accuracy to avoid violations of the constraints (3a)–(3c). As shown in Fig. 9, these expected scalings are well reproduced by both of our codes.

FIG. 9 (color online). CPU time needed to evolve BBHs from an initial separation r_i to a final separation $r_f = 10M$ using our new precession-averaged approach (purple circles) and the standard orbit-averaged approach (orange triangles). Each CPU time is averaged over $N = 100$ executions with isotropic initial spin orientation (flat distributions in $\cos\theta_1$, $\cos\theta_2$ and $\Delta\Phi$). Dashed lines show the expected scalings: $t \propto r_i^{3/2}$ for the orbit-averaged approach and $t \propto \log r_i$ for our new precession-averaged approach. These computations have been performed on a single core of a 2013 Intel i5-3470 3.20 GHz CPU.

In addition to the time needed to integrate Eq. (38), the precession-averaged approach must generate a final distribution for S (step 4 above), implying that the computational cost does not go to zero as $r_i \rightarrow r_f$. While this step makes the calculation of a single BBH inspiral nondeterministic and more expensive, precession averaging effectively reduces the dimensionality of the BBH population during the inspiral. If the n members of this final distribution for S are regarded as distinct binaries, the total number of integrations required to produce a fixed number of BBHs at r_f is reduced by a factor of n in the precession-averaged approach compared to the orbit-averaged approach.

IV. MORPHOLOGICAL PHASE TRANSITIONS

As BBHs inspiral on the radiation-reaction timescale, they can transition between the spin-precession morphologies described in Sec. II C. BBH spins predominantly circulate at large separations but increasingly transition into one of the two librating morphologies as spin-spin coupling becomes important (Sec. IV A). The probability of encountering one of these morphological phase transitions during the inspiral depends on the asymmetry between the masses

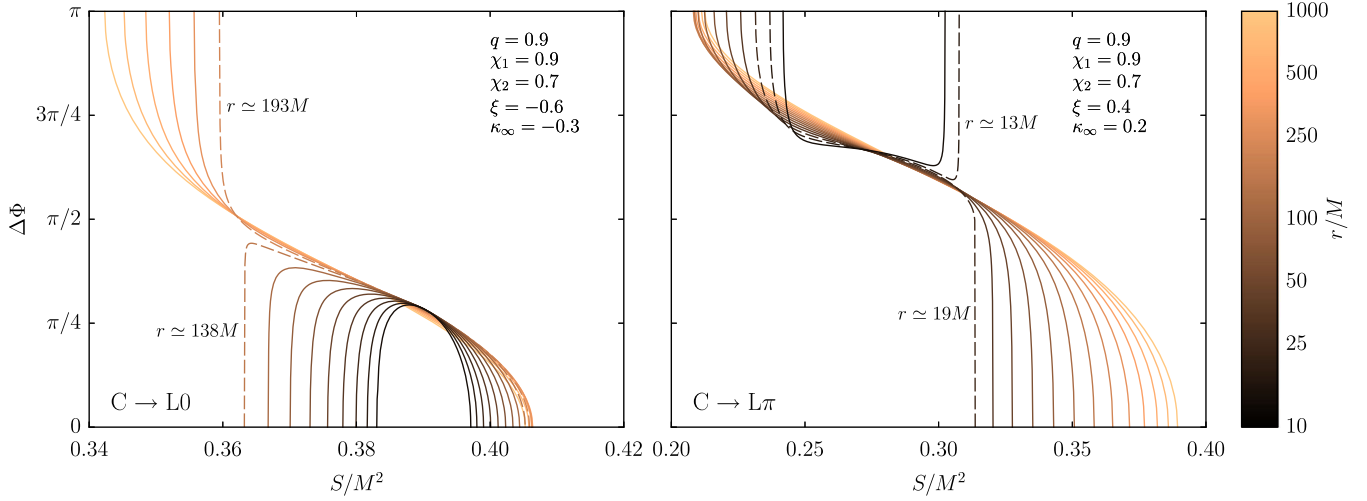

FIG. 10 (color online). Precessional solutions $\Delta\Phi(S)$ of Eqs. (20a)–(20d) as J and L evolve during inspirals according to Eq. (38). These solutions are colored according to the separation r/M as shown in the color bar on the right (orange/lighter for large separations and black/darker for small separations). Binaries in the left (right) panel transition from the circulating morphology to the morphology in which $\Delta\Phi$ librates about 0 (π) at the transition radius $r_{tr} \approx 152M$ ($18.9M$); separations bracketing the transition radius are marked with dashed lines. Parameters are set to the values indicated in the legends. An animated version of this figure is available online [55].

and the spin magnitudes of the two BBHs (Sec. IV B). Asymmetric binaries are more likely to circulate, while BBHs with comparable mass and spin ratios populate the librating morphologies. BBH spin morphologies at finite separations can be determined from their asymptotic spin orientations $\cos\theta_{i\infty}$ (or equivalently ξ and κ_∞) as discussed in Sec. IV C.

A. Phenomenology of phase transitions

As extensively discussed in Sec. II C, BBH spin precession can be unambiguously classified into one of three morphologies depending on the values of q , χ_1 , χ_2 , ξ , r (or L), and J . While the first four of these parameters remain constant throughout the inspiral, r and J evolve on the radiation-reaction timescale according to Eq. (38). Binaries may therefore change their precessional morphology while evolving towards merger. The boundaries between different morphologies (cf. Sec. II C) are set by the (anti)alignment condition $\sin\theta_i = 0$; the binary morphology changes whenever radiation reaction brings J and L to values that satisfy this condition [which can only occur on the effective-potential loop $\xi_\pm(S)$, as seen in Fig. 4]. Figure 10 shows two examples of these phase transitions. At the radii r_{tr} where phase transitions occur, $\Delta\Phi$ changes discontinuously either at S_- (left panel) or S_+ (right panel), causing the solutions $\Delta\Phi(S)$ of Eqs. (20a)–(20d) to transition between the qualitatively different shapes seen in the bottom panel of Fig. 3. The BBHs in the left (right) panel evolve from the circulating morphology to the morphology in which $\Delta\Phi$ oscillates about 0 (π).

A more complete phenomenology of phase transitions is illustrated in Fig. 11. The evolution of $\cos\theta_1$ and $\cos\theta_2$ along the inspiral is shown for a variety of initial conditions

$\cos\theta_{i\infty}$. At each separation r , the angles θ_i vary on the precession time within a finite range specified by the conditions $\xi = \xi_\pm(S)$ (cf. Fig. 3). These envelopes vary on the radiation-reaction time as J evolves according to Eq. (38); their width shrinks to a zero as $r/M \rightarrow \infty$ according to Eqs. (45a)–(45b), and tends to thicken at smaller separations because of the increasing importance of terms proportional to S^2 in Eqs. (20a)–(20d). Horizontal bars above each panel track the binary morphologies, which we label as **C**, **L0**, and **L π** for circulation, libration about $\Delta\Phi = 0$, and libration about $\Delta\Phi = \pi$. These morphologies change whenever one of the allowed ranges reach the boundaries $\cos\theta_i = \pm 1$.

All binaries circulate at large separation because the angles $\cos\theta_1$ and $\cos\theta_2$ are approximately constant (Sec. III B) and $\Delta\Phi$ from Eq. (20c) is monotonic in S , thus satisfying Eq. (21b). Some binaries (leftmost panels of Fig. 11) remain in the circulating morphology until the PN approximation breaks down ($r = 10M$). Other binaries undergo a single transition into a librating phase (middle columns of Fig. 11); $\Delta\Phi$ will oscillate about 0 (π) following this transition if the alignment condition $\sin\theta_i = 0$ is satisfied at S_- (S_+). Since $\cos\theta_1$ ($\cos\theta_2$) decreases (increases) monotonically with S [cf. Eqs. (20a)–(20d)], the above conditions can be summarized as

$$\cos\theta_1 = 1 \quad \text{or} \quad \cos\theta_2 = -1: \mathbf{C} \rightarrow \mathbf{L0}, \quad (49a)$$

$$\cos\theta_1 = -1 \quad \text{or} \quad \cos\theta_2 = 1: \mathbf{C} \rightarrow \mathbf{L\pi}. \quad (49b)$$

These phase transitions were seen in previous (orbit-averaged) simulations [37] and referred to as *spin locking*, because the BBH spins locked into libration about the

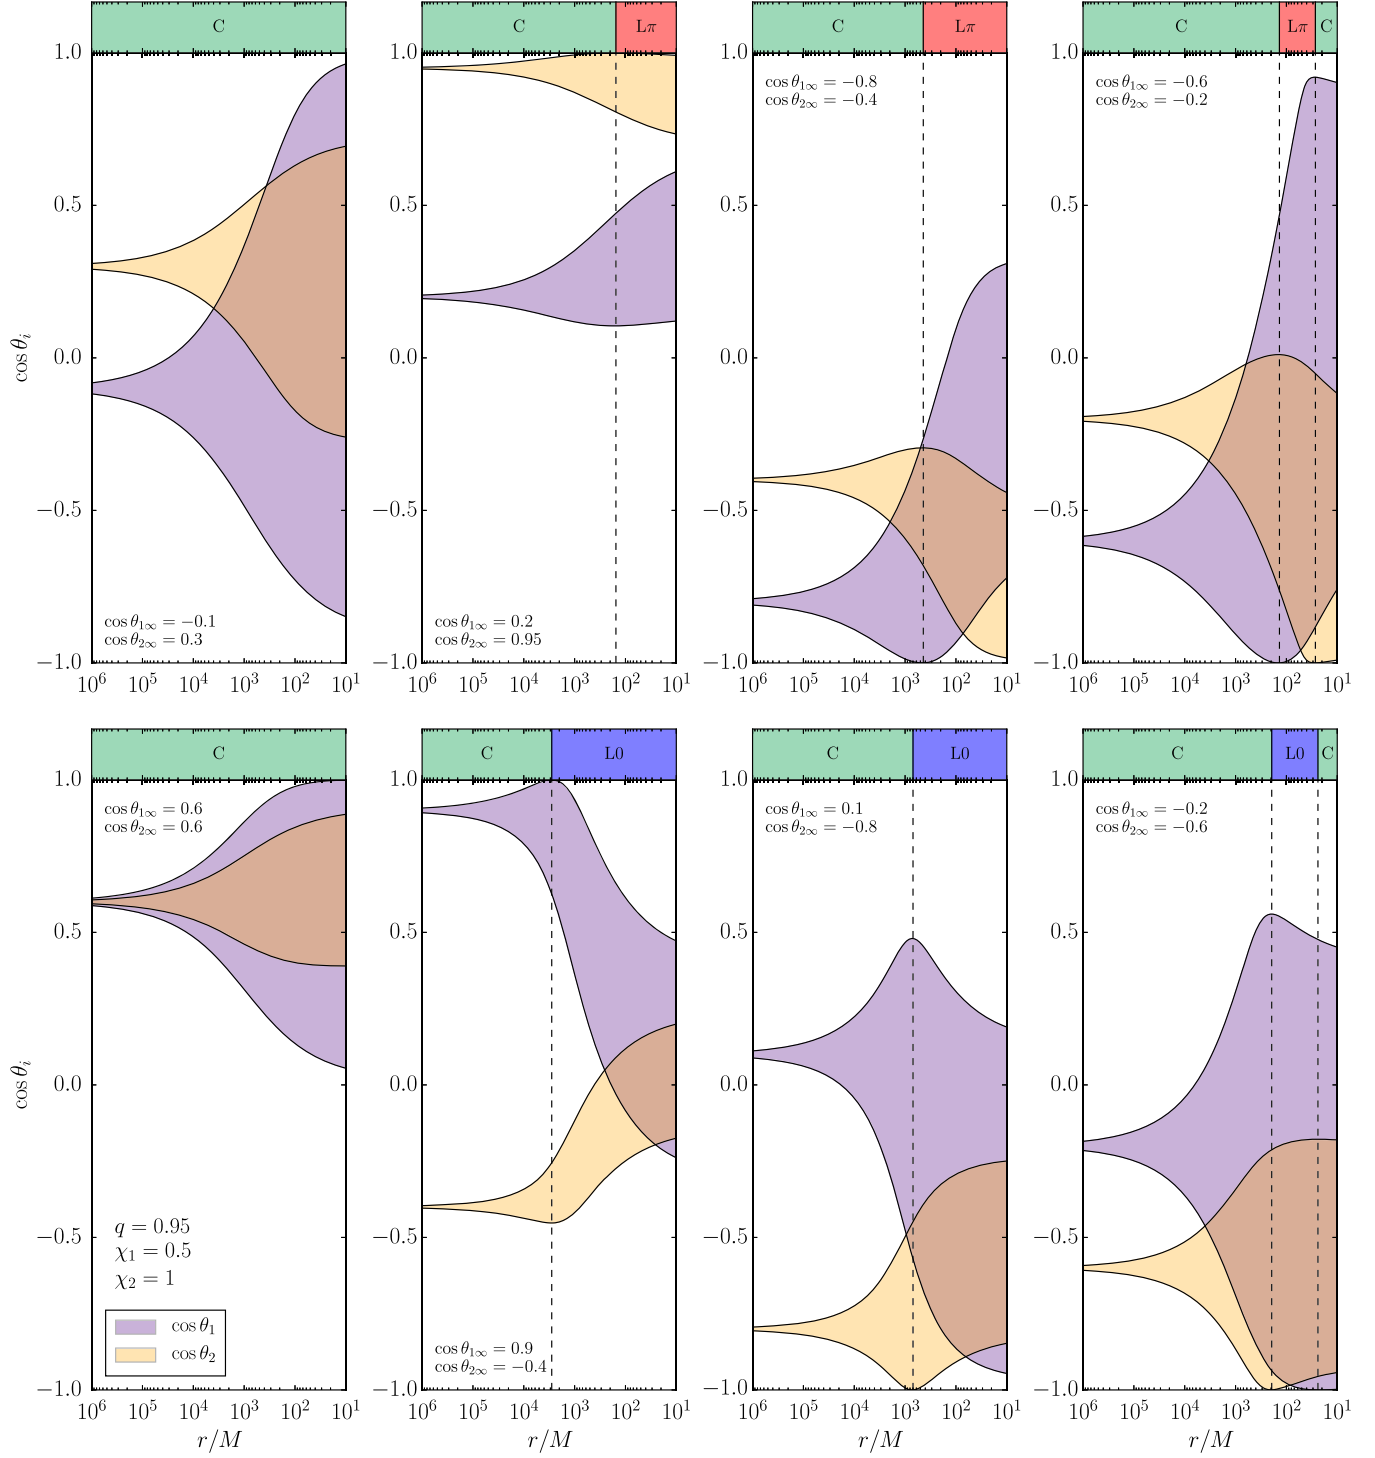

FIG. 11 (color online). Evolution of the spin morphology and the allowed ranges of the spin angles θ_i over a precession cycle as functions of the binary separation r . Each panel shows the range of $\cos \theta_1$ (purple/darker) and $\cos \theta_2$ (orange/lighter) for different initial conditions $\cos \theta_{i\infty}$. The current morphology is tracked by the horizontal bar above each panel. Morphologies are indicated as **C** (green) for circulating, **L0** (blue) for $\Delta\Phi$ librating about 0, and **L π** (red) for $\Delta\Phi$ librating about π . The morphology changes whenever $\cos \theta_i = \pm 1$ (vertical dashed lines). BBHs in the leftmost column do not undergo any transitions in the PN regime; one transition into a librating morphology occurs for BBHs in the center columns; two transitions (circulating to librating, librating to circulating) occur for BBHs in the rightmost column. The mass ratio and spin magnitudes are $q = 0.95$, $\chi_1 = 0.5$, and $\chi_2 = 1$ in all panels.

spin-orbit resonances at ξ_{\min} and ξ_{\max} . As the librating binaries continue to inspiral, some may transition back into the circulating phase, as pictured in the rightmost column of Fig. 11. The conditions for this second transition are

$$\cos \theta_1 = -1 \quad \text{or} \quad \cos \theta_2 = 1: \mathbf{L0} \rightarrow \mathbf{C}, \quad (50a)$$

$$\cos \theta_1 = 1 \quad \text{or} \quad \cos \theta_2 = -1: \mathbf{L\pi} \rightarrow \mathbf{C}. \quad (50b)$$

As discussed further in Sec. IV B below, this second phase transition occurs in the PN regime ($r \gtrsim 10M$) only in some corners of the parameter space ($q \lesssim 1$ and $\chi_1 \neq \chi_2$). We have not found any additional transitions in the PN regime, but multiple transitions may occur at the smaller separations accessible to numerical-relativity simulations.

B. Dependence on mass and spin asymmetry

The asymmetry in the masses m_i and spin magnitudes χ_i determines which of the eight scenarios depicted in Fig. 11 a binary will experience during its inspiral. The alignment conditions $\sin \theta_1 = 0$ and $\sin \theta_2 = 0$ tend to be satisfied at similar values of ξ for symmetric binaries ($q \rightarrow 1$ and $\chi_1 \approx \chi_2$), shrinking the circulating (green) region in the left panel of Fig. 4 and enhancing the fraction of librating binaries.

This point is illustrated in Fig. 12 below, which shows the fraction of isotropic binaries in each of the three morphologies as functions of the binary separation. Each panel is computed by averaging over a sample of binaries isotropically distributed at large separations (flat distributions in $\cos \theta_{1\infty}$ and $\cos \theta_{2\infty}$); all binaries in each sample share the same mass ratio and spin magnitudes. As the separation decreases, binaries transition from the circulating to librating morphologies. The fraction of binaries experiencing these transitions strongly depends on the mass ratio q . If the mass ratio is low ($q \lesssim 0.6$), most binaries remain circulating down to very small separations $r \sim 10M$. Comparable-mass binaries ($q \gtrsim 0.6$) are more likely to undergo a phase transition in the PN regime. The typical transition radius r_{tr} at which these phase transitions occur is also very sensitive to the mass ratio [36,37]; transitions occur in the very late inspiral for low mass ratios while r_{tr} can be as large as $10^5 M$ for $q \approx 0.99$. Very long evolutions are needed to capture all of the morphological transitions for nearly equal-mass binaries; such long inspirals are prohibitively expensive in the standard orbit-averaged approach (as seen in Fig. 9) but can easily be calculated within our new precession-averaged formalism.

A more extensive exploration of how BBH spin morphology depends on the binary parameters is shown in Fig. 13 and Table I. Isotropic distributions at $r/M = \infty$ are evolved down to $r = 10M$, where their morphologies

are determined; as shown in the upper panel of Fig. 8, these initially isotropic distributions remain isotropic at smaller separations. The fraction of binaries in each morphology at $r = 10M$ is shown as functions of q for a grid of values of the spin magnitudes χ_1 and χ_2 . As was already seen in Fig. 12, the likelihood of phase transitions depends on the mass ratio q ; more librating binaries are found for comparable-mass BBHs at any fixed separation.

Spin magnitudes also affect the fraction of BBHs in each morphology. As one moves along the diagonal of Fig. 13 in the direction of increasing $\chi_1 = \chi_2$, a slightly higher fraction of binaries are found in librating morphologies because of increased spin-spin coupling [37]. The corner of the parameter space characterized by mass symmetry and spin asymmetry ($q \rightarrow 1$ and $\chi_1 \neq \chi_2$) presents a peculiar phenomenology, as seen in the right panels of Fig. 12, where the fraction of binaries in each morphology approaches constant values for $r \lesssim 1000M$. This behavior can be explained by recognizing that in this region of parameter space binaries may undergo two morphological transitions in the PN regime, as seen in the rightmost panels of Fig. 11. The number of binaries experiencing their first phase transition from circulation to libration is nearly canceled by the number of binaries undergoing a second phase transition back to the circulating morphology, leading to almost constant fractions of binaries in each morphology. This effect also accounts for the kinks in the morphology fractions at $q \approx 0.9$ in the off-diagonal ($\chi_1 \neq \chi_2$) panels of Fig. 13.

C. Predicting spin morphology at small separations

We described in great detail in Sec. II C how to determine the BBH spin morphology from the binary parameters at a given separation, but astrophysical BBHs are often formed at much larger separations than where we are interested in observing them. Although BBHs can be efficiently evolved to smaller separations using the precession-averaged approach described in Sec. III C, we can in fact predict the spin morphology at a final separation r_f based solely upon the asymptotic values of $\theta_{1\infty}$ and $\theta_{2\infty}$ [or equivalently ξ and κ_∞ according to Eqs. (45a)–(45b)] without the need to integrate dJ/dL down to r_f . This can be achieved by recognizing that the curves in the $\cos \theta_{1\infty} - \cos \theta_{2\infty}$ plane separating the final morphologies at r_f correspond to BBHs experiencing phase transitions at r_f , i.e. binaries for which $\cos \theta_i(r_f) = \pm 1$. These binaries constitute the four borders of the $\cos \theta_1 - \cos \theta_2$ plane at r_f ; using our expression for dJ/dL in Eq. (38) to integrate BBHs along these borders out to $r/M \rightarrow \infty$, we obtain four curves in the $\cos \theta_{1\infty} - \cos \theta_{2\infty}$ plane, as seen in Fig. 14. These curves define regions **I** and **II** in the $\cos \theta_{1\infty} - \cos \theta_{2\infty}$ plane with the following boundaries:

FIG. 12 (color online). The fraction f of isotropic binaries in each of the three precessional morphologies as functions of the binary separation. Each panel refers to different values of q , χ_1 and χ_2 as indicated in the legends. The fraction of binaries in which $\Delta\Phi$ circulates (green, middle region of each panel), oscillates about 0 (blue, bottom region of each panel), or oscillates about π (red, top region of each panel) is shown as the binary orbit shrinks, with dashed lines separating the different morphologies. The fraction of binaries in librating morphologies generally grows during the inspiral; this growth is stronger as $q \rightarrow 1$ but may stall for nearly equal masses and $\chi_1 \neq \chi_2$, as seen in panels in the right column.

FIG. 13 (color online). The fraction f of isotropic BBHs for which $\Delta\Phi$ circulates (green, middle region), oscillates about 0 (blue, bottom region), or oscillates about π (red, top region) at a binary separation $r = 10M$ as functions of the mass ratio q . Dashed lines separate the different morphologies. Each panel corresponds to a different value of χ_1 (columns) and χ_2 (rows). The fraction of BBHs in librating morphologies increases as the mass asymmetry decreases ($q \rightarrow 1$). For nearly equal masses ($q \gtrsim 0.9$), asymmetry in the spin magnitudes increases the fraction of binaries in the circulating morphology as can be seen by comparing panels on and off the diagonal. Some data used in this plot are listed in Table I. The website [55] contains an animated version of this figure, where the panels are shown at decreasing binary separations.

TABLE I. Fractions of isotropic BBHs in each of the three precessional morphologies (**L0**: $\Delta\Phi$ oscillates about 0, **C**: $\Delta\Phi$ circulates, **L π** : $\Delta\Phi$ oscillates about π) at $r = 10M$ as shown in Fig. 13. For a grid of values in χ_1 (columns), χ_2 (rows) and, q (first column in each mini-table), we report the fraction of binaries in each morphology. The sum of the three fractions may differ from unity because of rounding errors.

- I.** $\cos\theta_{1\infty} = +1$, $\cos\theta_{2\infty} = -1$,
 $\cos\theta_1(r_f) = +1$, $\cos\theta_2(r_f) = -1$;
II. $\cos\theta_{1\infty} = -1$, $\cos\theta_{2\infty} = +1$,
 $\cos\theta_1(r_f) = -1$, $\cos\theta_2(r_f) = +1$.

The final morphology at r_f for each point in the $\cos\theta_{1\infty} - \cos\theta_{2\infty}$ plane is determined by whether or not that point is contained in the two regions:

- (i) Outside both region **I** and region **II**: $\Delta\Phi$ circulates (no phase transitions, plain green in Fig. 14).
(ii) Inside region **I** but not region **II**: $\Delta\Phi$ oscillates about 0 (one phase transition, blue in Fig. 14).

(iii) Inside region **II** but not region **I**: $\Delta\Phi$ oscillates about π (one phase transition, red in Fig. 14).

(iv) Inside both region **I** and region **II**: $\Delta\Phi$ circulates (two phase transitions, hatched green in Fig. 14).

These conditions on the final morphology are consistent with the criteria for phase transitions given in Eqs. (49a)–(49b) and (50a)–(50b). Once the boundaries of regions **I** and **II** have been established we can determine the final morphology of *any* BBH from its initial conditions at astrophysically large separations without further need to integrate dJ/dL down to r_f . A binary with spin orientations lying in the green, red or blue region of Fig. 14 at large

FIG. 14 (color online). Spin morphologies at $r_f = 10M$ as functions of the asymptotic values of the spin angles $\theta_{i\infty}$. The mass ratio q and spin magnitudes χ_i for each panel are indicated in the legends. Evolving BBHs along the four lines $\cos\theta_i = \pm 1$ at r_f out to $r/M \rightarrow \infty$ using our new precession-averaged approach yields the dashed curves separating the different final morphologies: $\Delta\Phi$ oscillates about 0 (blue), oscillates about π (red), circulates without ever having experienced a phase transition (plain green), or circulates after having experienced a phase transition to libration and then a second phase transition back to circulation (hatched green). The morphology within each region defined by the dashed boundaries is determined by which of the conditions $\cos\theta_i = \pm 1$ these boundaries satisfy, as described in Sec. IV C. The points show the locations of binaries in the $\cos\theta_1 - \cos\theta_2$ plane at r_f and are colored by their morphology at that separation [$\Delta\Phi$ oscillates about 0 (blue circles), oscillates about π (green squares), or circulates (red triangles)]. Because morphology depends on $\Delta\Phi$ in addition to θ_1 and θ_2 at finite separation, the projection onto the $\cos\theta_1 - \cos\theta_2$ plane can lead points of different morphologies to occur at the same positions, particularly for comparable-mass binaries $q \approx 1$ where the θ_i 's oscillate with greater amplitude. The website [55] contains an animated version of this figure in which r_f evolves.

separations will be found with $\Delta\Phi$ circulating, oscillating about 0 or oscillating about π at the end of the inspiral.

Measuring BBH spin morphology directly offers several advantages over explicitly measuring the spin angles θ_1 , θ_2 and $\Delta\Phi$. Spin morphology encodes information about BBH spin precession but is more robust than the spin angles in that it only varies on the radiation-reaction time (being a function of L , J , and ξ). Measurement of only the two angles θ_1 and θ_2 at small separations constrains neither the morphology at small separations nor the initial conditions at large separations, as can be seen from the scatter points in Fig. 14, which show an isotropic sample of binaries at r_f . Points corresponding to the circulating and both librating morphologies lie right on top of each other in this plot, evidence of both the importance of the third angle $\Delta\Phi$

and the large oscillations in θ_i at small separations seen in Fig. 11. By contrast, spin morphology is a direct memory of a BBH's initial position in the $\cos\theta_{1\infty} - \cos\theta_{2\infty}$ plane, as seen in Fig. 14. Astrophysical scenarios of BBH formation can favor some regions in this plane over others [40], implying that GW observations of spin morphology can constrain BBH formation [41].

V. DISCUSSION

BBHs evolve on three distinct timescales: the orbital time t_{orb} , the precession time t_{pre} , and the radiation-reaction time t_{RR} . In the PN regime ($r \gg r_g$), these timescales obey a strict hierarchy: $t_{\text{orb}} \ll t_{\text{pre}} \ll t_{\text{RR}}$. All of the parameters needed to describe BBHs evolve on a distinct

timescale: the vectorial binary separation \mathbf{r} on t_{orb} , the angular-momentum directions $\hat{\mathbf{L}}$ and $\hat{\mathbf{S}}_i$ on t_{pre} , and the orbital-angular-momentum magnitude L and total angular momentum \mathbf{J} on t_{RR} . The mass ratio q and spin magnitudes S_i remain constant throughout the inspiral. Expanding on our previous paper [28], we exploit this timescale hierarchy and conservation of the projected effective spin ξ [56,57] throughout the inspiral to solve the orbit-averaged 2PN equations of BBH spin precession given by Eqs. (25a)–(25b). The solutions given by Eqs. (20a)–(20d) for the three angles θ_1 , θ_2 , and $\Delta\Phi$ that specify the relative orientations of \mathbf{L} , \mathbf{S}_1 , and \mathbf{S}_2 are remarkably simple and are given parametrically in terms of a single variable, the total-spin magnitude S , that evolves on t_{pre} .

These solutions fully determine how the relative orientations of the three angular momenta evolve over a precession cycle as S oscillates back and forth between extrema S_{\pm} . We find that spin precession can be classified into three distinct morphologies depending on whether $\Delta\Phi$ oscillates about 0, oscillates about π , or circulates through the full range $[-\pi, +\pi]$ over a precession cycle. For BBHs with a given mass ratio q and spin magnitudes S_i , the precessional morphology at a binary separation r is determined by J and ξ , implying that the morphology only evolves on the radiation-reaction time t_{RR} . Spin-orbit coupling dominates over the higher-PN-order spin-spin coupling at large separations implying that all BBHs formed at such large separations begin in the circulating morphology. Since ξ is constant to high accuracy throughout the inspiral, evolving our solutions (20a)–(20d) and their associated morphology to smaller separations (lower values of L) only requires an expression for dJ/dL due to radiation reaction. All previous studies of radiation reaction have relied on orbit-averaged expressions for $d\mathbf{L}_{\text{RR}}/dt$ that must be integrated numerically with time steps $\Delta t \lesssim t_{\text{pre}}$. Our new solutions (20a)–(20d) allow us to *precession average* these expressions to derive Eq. (38) for dJ/dL that can be integrated with a time step $t_{\text{pre}} \ll \Delta t' \lesssim t_{\text{RR}}$. The computational cost of calculating inspirals from an initial separation r_i in our new precession-averaged approach scales as $\log r_i$, leading to vast savings over the traditionally orbit-averaged approach (which scales as $r_i^{3/2}$) for the large initial separations relevant to astrophysical BBH formation.

Using our new expression for dJ/dL , we can evolve our initially circulating BBHs to smaller separations, where they may experience a phase transition to one of the two librating morphologies. Some of these librating BBHs may subsequently undergo a second phase transition back to circulation before reaching a binary separation $r = 10M$ below which the PN approximation itself begins to break

down. Our precession-averaged calculation of the inspiral agrees well with the orbit-averaged approach down to nearly this separation where small discrepancies appear because of dynamically generated inhomogeneity in the precessional phase as the timescale hierarchy fails. Unlike the angles θ_1 , θ_2 and $\Delta\Phi$, that vary rapidly on the precession time at small separations, the precession morphology at small separations is directly determined by the asymptotic values $\theta_{i\infty}$ of these angles at large separations, providing a memory of BBH formation potentially accessible to GW detectors.

Although this work focuses on BBH spin precession, our analysis also facilitates the calculation and interpretation of GW signals. Fast templates suitable for GW detection and parameter estimation are being developed using our new precessional solutions and precession-averaged equation for radiation reaction [78]. The insights underpinning our approach (most notably the use of a hierarchical coordinate system that better respects the separation of timescales intrinsic in the binary dynamics) are also helping us to assess whether the precessional morphology of BBHs in spin-orbit resonances can be reliably identified in the context of full GW parameter estimation [79]. Preliminary results indicate that BBH spin orientations can be significantly constrained at realistic signal-to-noise ratios, suggesting that observations of BBH spin precession as described in this work may soon provide a new window into the astrophysical origins of BBHs and general relativity itself.
